Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

As always, we would like to thank our families for their support during the writing of this book,
since it meant time away from them:

Ziad F. Issa:

My wife, Dana, and my sons, Tariq and Amr

John M. Miller:

My wife, Jeanne, and my children, Rebekah, Jordan, and Jacob

Douglas P. Zipes:

My wife, Joan, and my children, Debbie, Jeff, and David

We also thank the Elsevier support team that helped bring this edition to fruition.

Disturbances in cardiac rhythm occur in a large proportion of the population. Arrhythmias can have sequelae that range from life-shortening to inconsequential. Sudden cardiac deaths and chronic disability are among the most frequent serious complications resulting from arrhythmias.

The eleventh edition of *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine* includes an excellent section on rhythm disturbances carefully edited and largely written by Douglas Zipes and Gordon Tomaselli, the most accomplished and respected investigators and clinicians in this field. However, there are many subjects that simply cannot be discussed in sufficient detail, even in a 2000-page, densely packed book. For this reason, the current editors and I decided to commission a series of companions to the parent title. We were extremely fortunate to enlist Dr. Zipes' help in editing and writing *Clinical Arrhythmology and Electrophysiology*. Dr. Zipes, in turn, enlisted two talented collaborators, Drs. Ziad F. Issa and John M. Miller, to work with him to produce this excellent volume.

This third edition is superbly illustrated, with the number of figures and tables increasing substantially from its predecessor. What has not changed, however, is the very high quality of the content, which is accurate, authoritative, and clear; second, it is as up-to-date as last month's journals; and third, the writing style and illustrations are consistent throughout with little, if any, duplication. As this important branch of cardiology has grown, so has this book.

The first seven chapters ("Molecular Mechanisms of Cardiac Electrical Activity," "Cardiac Ion Channels," "Electrophysiological Mechanisms of Cardiac Arrhythmias," "Electrophysiological Testing: Tools and Techniques," "Conventional Intracardiac Mapping Techniques," "Advanced Mapping and Navigation Modalities," and "Ablation Energy Sources") provide a superb introduction to the field. This is followed by 24 chapters on individual arrhythmias, each following a similar outline. Here, the authors lead us from a basic understanding of the arrhythmia to its clinical recognition, natural history, and management. The latter is moving rapidly from being largely drug-based to device-based, although many patients receive combination device-drug therapy. These options, as well as ablation therapy, are clearly spelled out as they apply to each arrhythmia. The final chapter discusses the complications of catheter ablation of cardiac arrhythmias.

We are proud to include *Clinical Arrhythmology and Electrophysiology* as a companion to *Braunwald's Heart Disease*, and we are fully confident that it will prove to be valuable to cardiologists, internists, investigators, and trainees.

Eugene Braunwald, MD
Peter Libby, MD
Robert Bonow, MD
Douglas Mann, MD
Gordon Tomaselli, MD

PREFACE

The third edition of *Clinical Arrhythmology and Electrophysiology* maintains its unique style, written by just the three of us. Once again, we can “explain, integrate, coordinate, and educate in a comprehensive, cohesive fashion while avoiding redundancies and contradictions.” We liken it to a comprehensive travel guide written by an expert who has actually stayed in that unique hotel or eaten in that special restaurant. We have experienced the progress first-hand, from basic science to clinical application, and are able to pass on our experiences to you. In addition, as before, readers have the opportunity to delve deeper into basic mechanisms or invasive procedures...or not...depending on the level of interest.

We have thoroughly revised and updated all chapters. In addition, we have greatly expanded the book by increasing the total number of

pages from 700 to over 1100 and increased the number of figures to almost 1000 in print and over 200 online. A unique feature of our book are 74 new videos that take the reader into our electrophysiology labs to become a “fly on the wall” observing electrophysiology procedures. We believe the adage that “one picture is worth a thousand words,” and we invite you to learn with us during actual procedures.

Our textbook, written as a companion to the *Braunwald’s Heart Disease* series, is for learners of all stages. We hope you enjoy, learn, and expand your care of arrhythmia patients.

IONIC EQUILIBRIUM

The lipid bilayer of the cell membrane is hydrophobic and impermeable to water-soluble substances such as ions. Hence, for the hydrophilic ions to be able to cross the membrane, they need hydrophilic paths that span the membrane (i.e., pores), which are provided by transmembrane proteins called ion channels. Once a hydrophilic pore is available, ions move passively across the membrane, driven by two forces: the electrical gradient (voltage difference) and chemical gradient (concentration difference). The chemical gradient forces the ions to move from a compartment of a higher concentration to one of lower concentration. The electrical gradient forces ions to move in the direction of their inverse sign (i.e., cations [positively charged ions] move toward a negatively charged compartment, whereas anions [negatively charged ions] move toward a positively charged compartment). Because the chemical and electrical gradients can oppose each other, the direction of net ion movement will depend on the relative contributions of chemical gradient and electrical potential (i.e., the net electrochemical gradient), so that ions tend to move spontaneously from a higher to a lower electrochemical potential.¹

The movement of an ion down its chemical gradient in one direction across the cell membrane results in build-up of excess charge carried by the ion on one side of the membrane, which generates an electrical gradient that impedes (repels) continuing ionic movement in the same direction. When the driving force of the electrical gradient across the membrane becomes equal and opposite to the force generated by the chemical gradient, the ion is said to be in electrochemical equilibrium, and the net transmembrane flux (or current) of that particular ion is zero. In this setting, the membrane electrical potential is called the equilibrium potential (E_{ion}) ("reversal potential" or "Nernst potential") of that individual ion. Any further current flow would reverse the balance of forces and therefore reverse the current direction until equilibrium is restored, hence the name "reversal potential."² The E_{ion} for a given ion measures the voltage that the ion concentration gradient generates when it acts as a battery, and it depends on its concentration on either side of the membrane and the temperature. At membrane voltages more positive to the reversal potential of the ion, passive ion movement is outward, whereas it is inward at a membrane potential (E_m) more negative to the Nernst potential of that channel.¹

When multiple ions across a membrane are removed from their electrochemical equilibrium, each ion will tend to force the E_m toward

its own E_{ion} . The contribution of each ion type to the overall E_m at any given moment is determined by the instantaneous permeability of the plasma membrane to that ion. The larger the membrane conductance to a particular ion, the greater is the ability of that ion to bring the E_m toward its own E_{ion} . Hence the E_m is the average of the E_{ion} of all the ions to which the membrane is permeable, weighed according to the membrane conductance of each individual ion relative to the total ionic conductance of the membrane.¹

TRANSMEMBRANE POTENTIALS

All living cells, including cardiomyocytes, maintain a difference in the concentration of ions across their membranes. There is a slight excess of positive ions on the outside of the membrane and a slight excess of negative ions on the inside of the membrane, resulting in a difference in the electrical charge (i.e., voltage, potential difference, or electrical gradient) across the cell membrane, called the E_m (also known as membrane voltage or transmembrane potential). A membrane that exhibits an electrical gradient is said to be polarized.

In nonexcitable cells, and in excitable cells in their baseline states (i.e., not conducting electrical signals), the E_m is held at a relatively stable value, called the resting E_m . All cells have a negative resting E_m (i.e., the cytoplasm is electrically negative relative to the extracellular fluid), which arises from the interaction of ion channels and ion pumps embedded in the membrane that maintain different ion concentrations on the intracellular and extracellular sides of the membrane.

When an ion channel opens, it allows ion flux across the membrane that generates an electrical current (I). This current affects the E_m , depending on the membrane resistance (R), which refers to the ratio between the E_m and electrical current, as shown in Ohm's law: $E = I \times R$, or $R = E/I$. Resistance arises from the fact that the membrane impedes the movement of charges across it; hence the cell membrane functions as a *resistor* (i.e., when current is passed through the membrane, there is a voltage drop that is predictable from Ohm's law). Conductance describes the ability of a membrane to allow the flux of charged ions in one direction across the membrane. The more permeable the membrane is to a particular ion, the greater is the conductance of the membrane to that ion (Table 1.1). Membrane conductance (g) is the reciprocal of resistance: $g = 1/R$.

Because the lipid bilayer of the cell membrane is very thin, accumulation of charged ions on one side gives rise to an electrical force

TABLE 1.1 Definitions Related to Electrical Properties of Cell Membranes

Term	Unit	Definition
Charge (electric charge, Q)	Coulombs	<ul style="list-style-type: none"> The physical property of matter that causes it to experience a force (electrostatic attraction or repulsion) in the presence of other matter.
Voltage (potential difference, V)	Volt (V)	<ul style="list-style-type: none"> There are two types of electric charges: positive and negative. Like charges repel and unlike attract. A separation of unlike charge in space; the greater the amount of charge separated, the larger the voltage, and the greater the tendency for the charges to flow toward each other. Voltage is always measured at one point with respect to another point. There cannot be a voltage at one point in space. Voltage is the ability to drive an electric current across a resistance.
Current (I)	Amperes (A)	<ul style="list-style-type: none"> A flow of electrical charges.
Resistance (R)	Ohm (Ω)	<ul style="list-style-type: none"> A measure of the difficulty with which current flows in a circuit; the greater the difficulty, the greater the resistance.
Conductance (g)	Siemen (S)	<ul style="list-style-type: none"> A measure of the ease with which current flows in a circuit. Conductance is the reciprocal of the resistance.
Capacitance (C)	Farad	<ul style="list-style-type: none"> The ability of a body to store an electrical charge. A material with a large capacitance holds more electric charge at a given voltage, than one with low capacitance.
Membrane potential (transmembrane potential, membrane voltage, E_m)	Volt (V)	<ul style="list-style-type: none"> The difference in electrical potential between the interior and the exterior of a biological cell.
Equilibrium potential of an ion (E_{ion}) (reversal potential, Nernst potential)	Volt (V)	<ul style="list-style-type: none"> The value of the E_m at which diffusive and electrical gradients for a particular ion counterbalance, so that there is no net ion flow across the membrane (i.e., electrochemical equilibrium). In other words, equilibrium potential is the membrane potential necessary to maintain a given concentration difference or the membrane potential that will result from maintenance of a given concentration difference. An ion will be in electrochemical equilibrium if $E_m = E_{ion}$.
Ionic current (I_{ion})	Amperes (A)	<ul style="list-style-type: none"> Electrical current generated by the flux of charged ions across the cell membrane.
Capacitive current (nonfaradaic current, double-layer current)		<ul style="list-style-type: none"> The electric current generated by the movement of electrons toward and away from the surfaces of the cell membrane. This current does not involve movement of charged ions across the cell membrane, it only causes accumulation (or removal) of electrical charges on membrane surface.

(potential) that pulls oppositely charged particles toward the other side. Hence the cell membrane functions as a *capacitor* (i.e., capable of separating and storing charge). Although the absolute potential differences across the cell membrane are small, they give rise to enormous electrical potential gradients because they occur across a very thin surface. As a consequence, apparently small changes in E_m can produce large changes in potential gradient and powerful forces that are able to induce molecular rearrangement in membrane proteins, such as those required for opening and closing ion channels embedded in the cell membrane. The capacitance of the membrane is generally fixed and unaffected by the molecules that are embedded in it. In contrast, membrane resistance is highly variable and depends on the conductance of ion channels embedded in the membrane.³

The sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), and chloride (Cl^-) ions are the major charge carriers, and their movement across the cell membrane creates a flow of current that generates excitation and signals in cardiac myocytes. The electrical current generated by the flux of an ion across the membrane is determined by the membrane conductance to that ion (g_{ion}) and the potential (voltage) difference across the membrane. The potential difference represents the potential at which there is no net ion flux (i.e., the E_{ion}) and the actual E_m : current = $g_{ion} \times (E_m - E_{ion})$.

By convention, an inward current increases the electropositivity within the cell (i.e., causes depolarization of the E_m [to become less negative]) and can result from either the movement of positively charged ions (most commonly Na^+ or Ca^{2+}) into the cell or the efflux of nega-

tively charged ions (e.g., Cl^-) out of the cell. An outward current increases the electronegativity within the cell (i.e., causes hyperpolarization of the E_m [to become more negative]) and can result from either the movement of anions into the cell or the efflux of cations (most commonly K^+) out of the cell.

Opening and closing of ion channels can induce a departure from the relatively static resting E_m , which is called *depolarization* if the interior voltage rises (becomes less negative) or *hyperpolarization* if the interior voltage becomes more negative. The most important ion fluxes that depolarize or repolarize the membrane are passive (i.e., the ions move down their electrochemical gradient without requiring the expenditure of energy), occurring through transmembrane ion channels. In excitable cells a sufficiently large depolarization can evoke a short-lasting all-or-none event called an *action potential*, in which the E_m very rapidly undergoes specific and large dynamic voltage changes.

Both resting E_m and dynamic voltage changes such as the action potential are caused by specific changes in membrane permeabilities for Na^+ , K^+ , Ca^{2+} , and Cl^- , which, in turn, result from concerted changes in functional activity of various ion channels, ion transporters, and ion exchangers.

CARDIAC ACTION POTENTIAL

During physiological electrical activity, the E_m is a continuous function of time. The current flowing through the cell membrane, at each instant, is provided by multiple channels and transporters carrying charge in

opposite directions because of their different ion selectivity. The algebraic summation of these contributions is referred to as net transmembrane current.

The cardiac action potential reflects a balance between inward and outward currents. When a depolarizing stimulus (typically generated by an electric current from an adjacent cell) abruptly changes the E_m of a resting cardiomyocyte to a critical value (the threshold level), the properties of the cell membrane and ion conductances change dramatically, precipitating a sequence of events involving the influx and efflux of multiple ions that together produce the action potential of the cell. In this fashion an electrical stimulus is conducted from one cell to the cells adjacent to it.⁴

Unlike skeletal muscle, cardiac muscle is electrically coupled so that the wave of depolarization propagates from one cell to the next, independent of neuronal input. The heart is activated by *capacitive currents* generated when a wave of depolarization approaches a region of the heart that is at its resting potential. Unlike ionic currents, which are generated by the flux of charged ions across the cell membrane, capacitive currents are generated by the movement of electrons toward and away from the surfaces of the membrane. These electrotonic potential changes are passive and independent of membrane conductance. The resulting decrease in positive charge at the outer side of the cell membrane reduces the negative charge on the intracellular surface of the membrane. These charge movements, which are carried by electrons, generate a capacitive current. When an excitatory stimulus causes the E_m to become less negative and beyond a threshold level (approximately -65 mV for working atrial and ventricular cardiomyocytes), Na^+ channels activate (open) and permit an inward Na^+ current (I_{Na}), resulting in a rapid shift of the E_m to a positive voltage range. This event triggers a series of successive opening and closure of selectively permeable ion channels. The direction and magnitude of passive movement (and the resulting current) of an ion at any given transmembrane voltage are determined by the ratio of the intracellular and extracellular concentrations and the reversal potential of that ion, with the net flux being larger when ions move from the more concentrated side.

The “threshold potential” is the lowest E_m at which opening of enough Na^+ channels (or Ca^{2+} channels in the setting of nodal cells) is able to initiate the sequence of channel openings needed to generate a propagated action potential. Small (subthreshold) stimuli depolarize the membrane in proportion to the strength of the stimulus and cause only local responses because they do not open enough Na^+ channels to generate depolarizing currents large enough to activate nearby resting cells (i.e., insufficient to initiate a regenerative action potential). On the other hand, when the stimulus is sufficiently intense to reduce the E_m to a threshold value, regenerative action potential results, whereby intracellular movement of Na^+ depolarizes the membrane more, a process that increases conductance to Na^+ more, which allows more Na^+ to enter, and so on. In this fashion the extent of subsequent depolarization becomes independent of the initial depolarizing stimulus, and more intense stimuli do not produce larger action potential responses; rather, an all-or-none response results.⁴

Electrical changes in the action potential follow a relatively fixed time and voltage relationship that differs according to specific cell types. Although the entire action potential takes only a few milliseconds in nerve cells, the cardiac action potential lasts several hundred milliseconds. The course of the action potential can be divided into five phases (numbered 0 to 4). Phase 4 is the resting E_m , and it describes the E_m when the cell is not being stimulated.

During the cardiac action potential, membrane voltages fluctuate in the range of -94 to $+30$ mV (Fig. 1.1). With physiological external K^+ concentration, the reversal potential of K^+ (E_K) is approximately -94 mV, and passive K^+ movement during an action potential is out of

the cell. On the other hand, because the calculated reversal potential of a cardiac Ca^{2+} channel (E_{Ca}) is $+64$ mV, passive Ca^{2+} flux is into the cell.

In normal atrial and ventricular myocytes and in His-Purkinje fibers, action potentials have very rapid upstrokes, mediated by the fast inward I_{Na} . These potentials are called *fast response* potentials. In contrast, action potentials in the normal sinus and atrioventricular (AV) nodal cells and many types of diseased tissues have very slow upstrokes, mediated by a slow inward, predominantly L-type voltage-gated Ca^{2+} current (I_{CaL}), rather than by the fast inward I_{Na} (Fig. 1.2). These potentials have been termed *slow response* potentials.

Fast Response Action Potential

Phase 4: The Resting Membrane Potential

The E_m of resting atrial and ventricular cardiomyocytes remains steady throughout diastole. The resting E_m is caused by the differences in ionic concentrations across the membrane and the selective membrane permeability (conductance) to various ions. Large concentration gradients of Na^+ , K^+ , Ca^{2+} , and Cl^- across the cell membrane are maintained by the ion pumps and exchangers (Table 1.2).⁴

Under normal conditions, the resting membrane is most permeable to K^+ and relatively impermeable to other ions. K^+ has the largest resting membrane conductance (g_K is 100 times greater than g_{Na}) because of the abundance of open K^+ channels at rest, whereas Na^+ and Ca^{2+} channels are generally closed. Thus K^+ exerts the largest influence on the resting E_m . As a consequence, the resulting E_m is almost always close to the K^+ reversal potential (E_m approximates E_K). The actual resting E_m is slightly less negative than E_K because the cell membrane is slightly permeable to other ions.

The inwardly rectifying K^+ (Kir) channels underlie an outward K^+ current (I_{K1}) responsible for maintaining the resting potential near the E_K in atrial, His-Purkinje, and ventricular cells, under normal conditions. Kir channels preferentially allow currents of K^+ ions to flow into the cell with a strongly voltage-dependent decline of K^+ efflux (i.e., reduction of outward current) on membrane depolarization. As such, I_{K1} is a strong rectifier that passes K^+ currents over a limited range of E_m . At a negative E_m , I_{K1} conductance is much larger than that of any other current; thus it clamps the resting E_m close to the reversal potential for K^+ (E_K) (see Chapter 2 for detailed discussion on the concept of rectification). I_{K1} density is much higher in ventricular than in atrial myocytes, a feature that largely prevents the ventricular cell from having diastolic membrane depolarization and pacemaker activity. By contrast, I_{K1} is almost absent in sinus and AV nodal cells, thus allowing for relatively more depolarized resting diastolic potentials compared with atrial and ventricular myocytes (Table 1.3). The effect of outward K^+ current to resist membrane depolarization (keeping voltage fixed) is sometimes referred to as a voltage clamping effect.²

A unique property of Kir currents is the unusual dependence of rectification on extracellular K^+ concentration. Specifically, with an

TABLE 1.2 Intracellular and Extracellular Ion Concentrations and Equilibrium Potentials in Cardiomyocytes

Ion	Extracellular Concentration (mM)	Intracellular Concentration (mM)	Equilibrium Potential (mV)
Na^+	135–145	10	+70
K^+	3.5–5.0	155	−94
Ca^{2+}	2	0.0001	+132
Cl^-	87	30	−28

Fig. 1.1 Contribution of Depolarizing Inward and Repolarizing Outward Currents to the Atrial and Ventricular Action Potential (AP). The top panel from the atrial (*left*) and ventricular (*right*) myocytes. The five phases of the AP are labeled: 0 = upstroke of the AP represents depolarization of the membrane; 1 = initial repolarization; 2 = plateau phase; 3 = late repolarization; 4 = the resting (diastolic) phase. The rate of change of the AP is directly proportional to the sum of the underlying transmembrane ion currents (*lower panels*). Inward currents (*blue*) depolarize the membrane, whereas outward currents (*red*) contribute to repolarization. Compared with an atrial AP, the ventricular AP typically has longer duration, higher plateau potential (phase 2), and more negative resting membrane potential (phase 4). I_{Ca} , L-type Ca^{2+} current; I_{Na} , Na^+ current; I_{NCX} , Na^+ - Ca^{2+} exchanger; I_{Kr} , rapidly activating delayed rectifier K^+ current; I_{Ks} , slowly activating delayed rectifier K^+ current; I_{Kur} , ultrarapidly activating delayed rectifier K^+ current; I_{K1} , inward rectifier K^+ current; I_{to} , transient outward K^+ current. Action potential duration (msec)	100 to 300	100 to 300	100 to 300	300 to 500	200 to 300

AV, Atrioventricular.

increase in extracellular K^+ , the I_{K1} current-voltage relationship shifts nearly in parallel with the E_K and leads to a crossover phenomenon. One important consequence of such behavior is that at potentials positive to the crossover, K^+ conductance increases rather than decreases, against an expectation based on a reduced driving force for K^+ ions as a result of elevated extracellular K^+ concentration.⁵

The resting E_m is also powered by the Na^+ - K^+ adenosine triphosphatase (ATPase) (the Na^+ - K^+ pump), which helps to establish concentration gradients of Na^+ and K^+ across the cell membrane. Under physiological conditions, the Na^+ - K^+ pump transports two K^+ ions into the cell against its chemical gradient and three Na^+ ions outside against

its electrochemical gradient at the expense of one ATP molecule. Because the stoichiometry of ion movement is not 1:1, the Na^+ - K^+ pump is electrogenic and generates a net outward movement of positive charges (i.e., an outward current). At faster heart rates, the rate of Na^+ - K^+ pumping increases to maintain the same ionic gradients, thus counteracting the intracellular gain of Na^+ and loss of K^+ with each depolarization.

Ca^{2+} does not contribute directly to the resting E_m because the voltage-activated Ca^{2+} channels are closed at the hyperpolarized resting E_m . However, changes in intracellular free Ca^{2+} concentration can affect other membrane conductance values. Increases in intracellular Ca^{2+}

levels can stimulate the $\text{Na}^+\text{-Ca}^{2+}$ exchanger ($I_{\text{Na-Ca}}$), which exchanges three Na^+ ions for one Ca^{2+} ion; the direction depends on the Na^+ and Ca^{2+} concentrations on the two sides of the membrane and the E_m difference. At resting E_m and during a spontaneous sarcoplasmic reticulum Ca^{2+} release event, this exchanger would generate a net Na^+ influx, possibly causing transient membrane depolarizations.

Phase 0: The Upstroke—Rapid Depolarization

On excitation of an atrial, ventricular, or Purkinje cardiomyocyte by electrical stimuli from adjacent cells, its resting E_m (approximately -85 mV) depolarizes, leading to opening (activation) of Na^+ channels from its resting (closed) state and enabling a large and rapid influx of Na^+ ions (inward I_{Na}) into the cell down their electrochemical gradient. As a consequence of increased Na^+ conductance, the excited membrane no longer behaves like a K^+ electrode (i.e., exclusively permeable to K^+) but more closely approximates an Na^+ electrode, and the E_m moves toward the E_{Na} (see Table 1.2). Once an excitatory stimulus depolarizes the E_m beyond the threshold for activation of Na^+ channels (approximately -65 mV), the activated I_{Na} is regenerative and no longer depends on the initial depolarizing stimulus. As a consequence, the influx of Na^+ ions further depolarizes the membrane and thereby increases conductance to Na^+ more, which allows more Na^+ to enter the cell (thus “regenerative”).⁶

Normally, activation of Na^+ channels is transient; fast inactivation (closing of the channel pore) starts simultaneously with activation, but because inactivation is slightly delayed relative to activation, the channels remain transiently (less than 1 millisecond) open to conduct I_{Na} during phase 0 of the action potential before it closes. In addition, the influx of Na^+ into the cell increases the positive intracellular charges and reduces the driving force for Na^+ . When the E_{Na} is reached, no further Na^+ ions enter the cell.

The rate at which depolarization occurs during phase 0 (i.e., the maximum rate of change of voltage over time [dV/dt_{max}]) is a reasonable approximation of the rate and magnitude of Na^+ entry into the cell and a determinant of conduction velocity for the propagated action potential (see later).

The threshold for activation of I_{CaL} is approximately -30 to -40 mV. Although I_{CaL} is normally activated during phase 0 by the regenerative depolarization caused by the fast I_{Na} , I_{CaL} is much smaller than the peak I_{Na} . Furthermore, the amplitude of I_{CaL} is not maximal near the action potential peak because of the time-dependent nature of I_{CaL} activation, as well as the low driving force ($E_m - E_{\text{Ca}}$) for I_{CaL} . Therefore I_{CaL} contributes little to the action potential until the fast I_{Na} is inactivated, after completion of phase 0. As a result, I_{CaL} affects mainly the plateau of action potentials recorded in atrial and ventricular muscle and His-Purkinje fibers. On the other hand, I_{CaL} plays a prominent role in the upstroke of slow response action potentials in partially depolarized cells in which the fast Na^+ channels have been inactivated.

Phase 1: Early Repolarization

Phase 0 is followed by phase 1 (early repolarization), during which the membrane repolarizes rapidly and transiently to almost 0 mV (early notch), partly because of the inactivation of I_{Na} and concomitant activation of several outward currents. The transient outward K^+ current (I_{to}) is mainly responsible for phase 1 of the action potential. I_{to} rapidly activates (with time constants less than 10 milliseconds) by depolarization and then rapidly inactivates (25 to 80 milliseconds for the fast component of I_{to} [$I_{\text{to,f}}$], and 80 to 200 milliseconds for the slow component of I_{to} [$I_{\text{to,s}}$]). The influx of K^+ ions via I_{to} channels partially repolarizes the membrane, thus shaping the rapid repolarization (phase 1) of the action potential and setting the height of the initial plateau (phase 2) (see Fig. 1.1). In addition, an Na^+ outward current through

the $\text{Na}^+\text{-Ca}^{2+}$ exchanger operating in reverse mode likely contributes to this early phase of repolarization.⁴

Phase 2: The Plateau

Phase 2 (plateau) represents a delicate balance between the depolarizing inward currents (I_{CaL} and a small residual component of inward I_{Na}) and the repolarizing outward currents (ultrarapidly [I_{Kur}], rapidly [I_{Kr}], and slowly [I_{Ks}] activating delayed outward rectifying currents) (see Fig. 1.1). Phase 2 is the longest phase of the action potential, lasting tens (atrium) to hundreds of milliseconds (His-Purkinje system and ventricle). The plateau phase is unique among excitable cells and marks the phase of Ca^{2+} entry into the cell. It is the phase that most clearly distinguishes the cardiac action potential from the brief action potentials of skeletal muscle and nerve.^{4,7,8}

I_{CaL} is activated by membrane depolarization, is largely responsible for the action potential plateau, and is a major determinant of the duration of the plateau phase. I_{CaL} also links membrane depolarization to myocardial contraction. L-type Ca^{2+} channels activate on membrane depolarization to potentials positive to -40 mV. I_{CaL} peaks at an E_m of 0 to $+10$ mV and tends to reverse at $+60$ to $+70$ mV, following a bell-shaped current-voltage relationship.

Na^+ channels also make a contribution, although minor, to the plateau phase. After phase 0 of the action potential, some Na^+ channels occasionally fail to inactivate or exhibit prolonged opening or reopening repetitively for hundreds of milliseconds after variable and prolonged latencies, resulting in a small inward I_{Na} (with a magnitude of less than 1% of the peak I_{Na}). This persistent or “late” I_{Na} (I_{NaL}), along with I_{CaL} , helps to maintain the action potential plateau.⁹

I_{Kr} and I_{Ks} are activated at depolarized membrane potentials. I_{Kr} activates relatively fast (in the order of tens of milliseconds) on membrane depolarization, thus allowing outward diffusion of K^+ ions in accordance with its electrochemical gradient, but voltage-dependent inactivation thereafter is very fast. Hence only limited numbers of channels remain in the open state, whereas a considerable fraction resides in the nonconducting inactivated state. The fast voltage-dependent inactivation limits outward current through the channel at positive voltages and thus helps to maintain the action potential plateau phase that controls contraction and prevents premature excitation. However, as the voltage becomes less positive at the end of the plateau phase of repolarization, the channels recover rapidly from inactivation; this process leads to a progressive increase in I_{Kr} amplitudes during action potential phases 2 and 3, with maximal outward current occurring before the final rapid declining phase of the action potential.¹⁰

I_{Ks} , which is approximately 10 times larger than I_{Kr} , also contributes to the plateau phase. I_{Ks} activates in response to membrane depolarization to potentials positive to -30 mV and gradually increases during the plateau phase because its time course of activation is extremely slow, slower than any other known K^+ current. In fact, steady-state amplitude of I_{Ks} is achieved only with extremely long membrane depolarization. Hence the contribution of I_{Ks} to the net repolarizing current is greatest late in the plateau phase, particularly during action potentials of long duration. Importantly, although I_{Ks} activates slowly compared with action potential duration, it is also slowly inactivated. As heart rate increases, I_{Ks} increases because channel deactivation is slow and incomplete during the shortened diastole. This allows I_{Ks} channels to accumulate in the open state during rapid successive action potentials and mediate the faster rate of repolarization. Hence I_{Ks} plays an important role in determining the rate-dependent shortening of the cardiac action potential.⁵

I_{Kur} is detected only in human atria but not in the ventricles, such that it is the predominant delayed rectifier current responsible for atrial repolarization and is a basis for the much shorter duration of the action

potential in the atrium. I_{Kur} activates rapidly on depolarization in the plateau range and displays outward rectification, but it inactivates slowly during the time course of the action potential.

The Na^+ - Ca^{2+} exchanger operating in forward mode (three Na^+ ions in for one Ca^{2+} ion out) and the Na^+ - K^+ pump provide minor current components during phase 2.

Importantly, during the plateau phase, membrane conductance to all ions falls to rather low values. Thus less change in current is required near plateau levels than near resting potential levels to produce the same changes in E_m . In particular, K^+ conductance falls during the plateau phase as a result of inward rectification of I_{K1} (i.e., voltage-dependent decline of K^+ efflux and hence reduction of outward current) on membrane depolarization, in spite of the large electrochemical driving force on K^+ ions during the positive phase of the action potential (phases 0, 1, and 2). This property allows membrane depolarization following Na^+ channel activation, slows membrane repolarization, and helps to maintain a more prolonged cardiac action potential. This also confers energetic efficiency in the generation of the action potential.^{11,12}

Phase 3: Final Rapid Repolarization

Phase 3 is the phase of rapid repolarization that restores the E_m to its resting value. Phase 3 is mediated by the increasing conductance of the delayed outward rectifying currents (I_{Kr} and I_{Ks}), the inwardly rectifying K^+ currents (I_{K1} and acetylcholine-activated K^+ current [I_{KACH}]), and time-dependent inactivation of I_{CaL} (see Fig. 1.1). Final repolarization during phase 3 results from K^+ efflux through the I_{K1} channels, which open at potentials negative to -20 mV.⁴

Phase 4: Restoration of Resting Membrane Potential

During the action potential, Na^+ and Ca^{2+} ions enter the cell and depolarize the E_m . Although the E_m is quickly repolarized by the efflux of K^+ ions, restoration of transmembrane ionic concentration gradients to the baseline resting state is necessary. This is achieved by the Na^+ - K^+ ATPase (Na^+ - K^+ pump, which exchanges two K^+ ions inside and three Na^+ ions outside) and by the Na^+ - Ca^{2+} exchanger ($I_{\text{Na-Ca}}$) which exchanges three Na^+ ions for one Ca^{2+} ion).⁴

Reduction of cytosolic Ca^{2+} concentration during diastole is achieved by the reuptake Ca^{2+} by the sarcoplasmic reticulum via activation of the sarco/endoplasmic reticulum calcium-ATPase calcium pump (SERCA), in addition to extrusion across the sarcolemma via the Na^+ - Ca^{2+} exchanger. In the human heart under resting conditions, the time required for cardiac myocyte depolarization, contraction, relaxation, and recovery is approximately 600 milliseconds.

Regional Heterogeneity of the Action Potential

Substantial differences in expression levels of ion channels underlie the considerable heterogeneity in action potential duration and configuration between cardiomyocytes located in different regions of the heart. The characteristics of the action potential differ in atrial versus ventricular myocardium, as well as across the ventricular myocardial wall from endocardium, midmyocardium, to epicardium (see Fig. 1.2).

Atrioventricular Heterogeneity of the Action Potential

Compared with the atrium, ventricular myocytes maintain a slightly more hyperpolarized resting E_m (approximately -85 mV vs. -80 mV). In addition, the action potential duration is longer, the plateau phase reaches a more depolarized E_m (approximately $+20$ mV), and phase 3 repolarization curve is steeper in ventricular myocytes as compared with the atrial action potential (see Table 1.3).

The differences in action potential configuration between atria and ventricles are mainly related to differences in ionic current densities and ion channel expression (especially K^+ channels) between ventricular

and atrial myocytes. Although I_{Kr} and I_{Ks} densities are similar in atrial and ventricular myocytes, I_{Kur} is detected only in human atria and not in the ventricles. In fact, I_{Kur} is the predominant delayed rectifier current responsible for human atrial repolarization, with only small contribution of I_{Kr} and I_{Ks} .

Furthermore, the density of I_{to} is twofold higher in the atria compared with ventricular myocytes. In addition, I_{to} subtypes ($I_{to,f}$ and $I_{to,s}$) are differentially expressed in the heart. $I_{to,f}$ is the principal subtype expressed in human atrium. Conversely, $I_{to,s}$ is larger and $I_{to,f}$ is smaller in the ventricles compared with atrial tissue.⁸

The markedly higher densities of $I_{to,f}$ together with the expression of I_{Kur} accelerate the early phase of repolarization and lead to lower plateau potentials and shorter action potential durations in atrial as compared with ventricular cells.¹³

I_{K1} density is much higher in ventricular than in atrial myocytes, and this explains the steep repolarization phase in the ventricles (where the more abundant I_{K1} plays a larger role in accelerating the terminal portion of repolarization) and the shallower phase in the atria. Furthermore, the higher I_{K1} channel expression underlies the hyperpolarized resting E_m in ventricular myocytes, and prevents the ventricular cell from exhibiting pacemaker activity.¹⁴

Several other K^+ channels are atrial selective and potentially contribute significantly to the atrial, but not ventricular, action potential. These include I_{KACH} , two-pore K^+ channels (K_{2P}), and small-conductance Ca^{2+} -activated K^+ (SK) channels.

Ventricular Regional Heterogeneity of the Action Potential

Action potential differences exist among the different layers across the ventricular wall, between the left and right ventricles, and from the apical region to the base.

Three distinct action potential waveforms have been distinguished from three predominant cell types contributing to the transmural heterogeneity of ventricular repolarization: the epicardial, midmyocardial, and endocardial cardiomyocytes. The most notable differences among these three layers are the prominent phase 1 notch and the spike and dome morphology of epicardial and midmyocardial action potentials compared with endocardium. The action potential duration of epicardial myocytes is shorter than that of endocardial myocytes. The duration of the action potential is longest in midmyocardial myocytes.^{8,14}

The distinct notch phase in the action potential waveform of epicardial myocytes has mainly been attributed to the regional differences in I_{to} density across the myocardial wall. In human ventricles, I_{to} densities are much higher in the epicardium and midmyocardium than in the endocardium. Furthermore, although both $I_{to,f}$ and $I_{to,s}$ are expressed in the ventricle, $I_{to,f}$ is more prominent in the epicardium and midmyocardium than in the endocardium, whereas $I_{to,s}$ is mainly present in the endocardium and Purkinje cells. A prominent I_{to} -mediated action potential notch in ventricular epicardium but not endocardium produces a transmural voltage gradient during early ventricular repolarization that registers as a J wave or J point elevation on the electrocardiogram (ECG).^{8,14}

Some experimental studies in wedge preparations strongly suggest the presence of a subpopulation of cells in the midmyocardium (referred to as the M cells) that exhibits distinct electrophysiological (EP) properties, although the presence of M cells has not been consistently confirmed by intact heart experiments. The putative M cells appear to have the longest action potential duration across the myocardial wall, largely attributed to their weaker I_{Ks} current but stronger late I_{Na} and Na^+ - Ca^{2+} exchanger currents. Hence the M cells have been proposed to underlie the EP basis for transmural ventricular dispersion of repolarization and the T wave on the surface ECG, with the peak of the T wave (in wedge preparations) coinciding with the end of epicardial repolarization and

the end of the T wave coinciding with the end of repolarization of the M cells. Although the role of M cells under physiological conditions remains controversial, these cells appear to have a significant role in arrhythmogenesis under a variety of pathological conditions, such as the long QT and Brugada syndromes, secondary to exaggeration of transmural repolarization gradients.

In addition to the transmural action potential gradient that exists across the three layers of myocardium in the left and right ventricles, the right ventricular (RV) action potential duration overall is shorter and the spike and dome morphology is more pronounced compared with that of the left ventricle (LV). These differences have been attributed to higher I_{to} densities in the right than in the left ventricular myocytes.¹⁴

Evidence also suggests an apicobasal ventricular action potential heterogeneity. Action potential duration appears to be shorter in LV base compared with the apex. Larger I_{to} and I_{Ks} in apical compared with basal myocytes likely underlie those observations.¹⁴

Slow Response Action Potential

In normal atrial and ventricular myocytes and in the His-Purkinje fibers, action potentials have very rapid upstrokes mediated by the fast inward I_{Na} . These potentials are called fast response potentials. In contrast, action potentials in the normal sinus and AV nodal cells and many types of diseased tissue have very slow upstrokes, mediated predominantly by the slow inward I_{CaL} , rather than by the fast inward I_{Na} (see Fig. 1.2). These potentials have been termed *slow response potentials*.⁴

As noted, action potentials of pacemaker cells in the sinus and AV nodes are significantly different from those in working atrial and ventricular myocardium. Slow response action potentials are characterized by a more depolarized E_m at the onset of phase 4 (–50 to –65 mV), slow diastolic depolarization during phase 4, and reduced action potential amplitude. Furthermore, the rate of depolarization in phase 0 is much slower than that in the working myocardial cells, resulting in reduced conduction velocity of the cardiac impulse in the nodal regions (see Table 1.3). Cells in the His-Purkinje system can also exhibit phase 4 depolarization under special circumstances (when Na^+ channels are inactivated by pathological processes).

Phase 4: Diastolic Depolarization

The sinus and AV nodal cells lack the inward rectifier K^+ current (I_{K1}), which acts to stabilize the resting E_m in the normal working atrial and ventricular myocardium and Purkinje fibers. Sinus and AV nodal excitable cells exhibit a spontaneous, slow, and progressive decline in the E_m during diastole (spontaneous diastolic depolarization or phase 4 depolarization) that underlies normal automaticity and pacemaking function. Once this spontaneous depolarization reaches threshold (approximately –40 mV), a new action potential is generated.¹⁵

The ionic mechanisms responsible for diastolic depolarization and normal pacemaker activity in the sinus node are still controversial. Originally, a major role was attributed to the decay of the delayed K^+ conductance (an outward current) activated during the preceding action potential (the I_K -decay theory). This model of pacemaker depolarization lost favor upon the discovery of the “funny” current (I_f), sometimes referred to as the pacemaker current. I_f is a hyperpolarization-activated inward current that is carried largely by Na^+ and, to a lesser extent, K^+ ions. Once activated, I_f depolarizes the membrane to a level where the Ca^{2+} current activates to initiate an action potential.^{15,16}

Other ionic currents gated by membrane depolarization (i.e., I_{CaL} and T-type Ca^{2+} current [I_{CaT}]), nongated and nonspecific background leak currents, and a current generated by the Na^+ - Ca^{2+} exchanger have also been proposed to be involved in pacemaking. The “membrane

clock” (also referred to as the “voltage clock” or “ion channel clock”) refers to the time- and voltage-dependent membrane ion channels underlying pacemaking activity, including the decay of the outward rectifier K^+ current and the activation of several inward currents (I_f , I_{CaL} , I_{CaT} , and I_{Na}).

Newer evidence suggests that the sarcoplasmic reticulum, a major Ca^{2+} store in sinus nodal cells, can function as a physiological clock (the so-called calcium clock) within the cardiac pacemaker cells and has a substantial impact on late diastolic depolarization.^{15,17}

There remains some degree of uncertainty about the relative role of I_f versus that of intracellular Ca^{2+} cycling in controlling the normal pacemaker cell automaticity. Furthermore, the interactions between the membrane clock and the intracellular calcium clock and cellular mechanisms underlying this internal Ca^{2+} clock are not completely elucidated. A further debate has arisen around their individual (or mutual) relevance in mediating the positive and negative chronotropic effects of neurotransmitters. Nevertheless, these interactions are of fundamental importance for understanding the integration of pacemaker mechanisms at the cellular level (see Chapter 3 for detailed discussion on the mechanisms of automaticity and pacemaker activity).¹⁴

Phase 0: The Upstroke—Slow Depolarization

I_{K1} is almost absent in sinus and AV nodal cells, thus allowing for relatively more depolarized resting diastolic potentials (–50 to –65 mV) compared with atrial and ventricular myocytes and facilitating diastolic depolarization mediated by the inward currents (e.g., I_f). At the depolarized level of the maximum diastolic potential of pacemaker cells, most Na^+ channels are inactivated and unavailable for phase 0 depolarization. Consequently, action potential upstroke is mainly achieved by I_{CaL} .¹⁵

L-type Ca^{2+} channels activate on depolarization to potentials positive to –40 mV, and I_{CaL} peaks at 0 to +10 mV. The peak amplitude I_{CaL} is less than 10% that of I_{Na} , and the time required for activation and inactivation of I_{CaL} is approximately an order of magnitude slower than that for I_{Na} . As a consequence, the rate of depolarization in phase 0 (dV/dt) is much slower and the peak amplitude of the action potential is less than that in the working myocardial cells.

EXCITABILITY

Excitability of a cardiac cell describes the ease with which the cell responds to a stimulus with a regenerative action potential. A certain minimum charge must be applied to the cell membrane to elicit a regenerative action potential (i.e., the stimulus should be sufficiently intense to reduce the E_m to the threshold value). Excitability is inversely related to the charge required for excitation.

Excitability of a cardiac cell depends on the passive and active properties of the cell membrane. The passive properties include the membrane resistance and capacitance and the intercellular resistance. The most important determinant of reduced excitability is the reduced availability of Na^+ channels. The more negative the E_m is, the more Na^+ channels are available for activation, the greater the influx of Na^+ into the cell during phase 0, and the greater the conduction velocity. In contrast, membrane depolarization to levels of –60 to –70 mV can inactivate half the Na^+ channels, and depolarization to –50 mV or less can inactivate all the Na^+ channels, thereby rendering Na^+ channels unavailable for mediating an action potential upstroke and thus reducing tissue excitability (Fig. 1.3).

Reduced excitability is physiologically observed during the relative refractory period (occurring during phase 3 of the action potential, before full recovery of E_m). At less negative potentials of the cell membrane, a portion of Na^+ channels will still be inactivated and unavailable

Fig. 1.3 Cellular Excitability. Relationship between transmembrane action potential from single ventricular muscle fiber and excitability of fiber to cathodal stimulation. Amplitudes of peak sodium current (I_{Na}) and proportion of Na^+ channels in the resting state are depicted as a function of resting membrane potential. *I*, Inactivation of Na^+ channels; *R*, recovery of Na^+ channels. (Redrawn from Rosen MS, Wit AL, Hoffman BF. Electrophysiology and pharmacology of cardiac arrhythmias. I. Cellular electrophysiology of the mammalian heart. *Am Heart J*. 1974;88:380.)

for activation. As a result, initiation of a propagating action potential will require a larger-than-normal stimulus. Even then, I_{Na} and phase 0 of the resulting action potential are reduced, and conduction of a premature stimulus occurring during that period is slowed.

On the other hand, supernormal excitability can be observed during a brief period at the end of phase 3 of the action potential. During the supernormal period, excitation is possible in response to an otherwise subthreshold stimulus; that same stimulus fails to elicit a response earlier and later than the supernormal period. Two factors are responsible for supernormality: the availability of fast Na^+ channels and the proximity of the E_m to threshold potential. During the supernormal phase of excitability, the cell has recovered enough to respond to a stimulus (i.e., an adequate number of Na^+ channels is available for activation). At the same time, because the E_m is still reduced, it requires only a little additional depolarization to bring the fiber to threshold; thus a stimulus that is smaller than is normally required is now able to elicit an action potential. However, because Na^+ channels are still not fully activated, the resulting action potential is still somewhat reduced from normal in amplitude and propagation velocity.¹⁸ In general, the later the second stimulus comes, the more the Na^+ channels are reactivated, and the more rapid the upstroke of the second action potential.

Reduced membrane excitability can occur in certain pathophysiological conditions, including genetic mutations that result in loss of Na^+ channel function, Na^+ channel blockade with class I antiarrhythmic drugs, and acute myocardial ischemia.¹⁹

Action potentials with reduced upstroke velocity resulting from partial inactivation of Na^+ channels are called “depressed fast responses.” Importantly, refractoriness in cells with reduced E_m can outlast voltage recovery of the action potential (i.e., the cell can still be refractory or partially refractory after the resting E_m returns to its most negative value).

REFRACTORINESS

During a cardiac cycle, once an action potential is initiated, the cardiomyocyte becomes inexcitable to stimulation (i.e., unable to initiate another action potential in response to a stimulus of threshold intensity) for some duration of time (which is generally slightly shorter than the duration of the “true” action potential duration) until its membrane

Fig. 1.4 Cellular Refractory Periods. See text for details. (Redrawn from Rosen MS, Wit AL, Hoffman BF. Electrophysiology and pharmacology of cardiac arrhythmias. I. Cellular electrophysiology of the mammalian heart. *Am Heart J*. 1974;88:380.)

has repolarized to a certain level. With repolarization, Na^+ channels normally recover rapidly from inactivation (within 10 milliseconds) and are ready to open again. Refractoriness is determined, in part, by the action potential duration and the E_m , and the degree of refractoriness primarily reflects the number of Na^+ channels that have recovered from their inactive state. The period of refractoriness to stimulation is physiologically necessary for the mechanical function of the heart; it allows only gradual recovery of excitability, thus permitting relaxation of cardiac muscle before subsequent activation. In addition, the refractory period acts as a protective mechanism by preventing multiple, compounded action potentials from occurring (i.e., it limits the frequency of depolarization and heart rate). Therefore refractoriness is a determinant of susceptibility to arrhythmias. In general, shorter refractoriness facilitates reentry and arrhythmias.⁹

There are different levels of refractoriness during the action potential (Fig. 1.4). During the *absolute refractory period* (which extends over phases 0, 1, 2, and part of phase 3 of the action potential), no stimulus, regardless of its strength, can reexcite the cell. After the absolute refractory period, a stimulus can cause some cellular depolarization, but it does not lead to a propagated action potential. The sum of this period (which includes a short interval of phase 3 of the action potential) and the absolute refractory period is termed the *effective refractory period* (ERP, ending during phase 3 at an E_m of approximately -60 mV). The ERP is followed by the *relative refractory period*, which extends over the middle and late parts of phase 3 (at an E_m of approximately -60 mV during phase 3) to the end of phase 3 of the action potential. During the relative refractory period, initiation of a second action potential is more difficult but not impossible; a larger-than-normal stimulus can result in activation of the cell and lead to a propagating action potential (Fig. 1.5). However, the upstroke of the new action potential is less steep and of lower amplitude and its conduction velocity is reduced compared with normal. As noted, there is a brief period in phase 3, the supernormal period, during which excitation is possible in response to an otherwise subthreshold stimulus (supernormal excitability).¹⁸

In pacemaking tissues, I_{Na} is predominantly absent and excitability is mediated by the activation of I_{CaL} . After inactivation, the transition of Ca^{2+} channels from the inactivated to the closed resting state (i.e., recovery from inactivation) is relatively slow. The time constant for recovery from inactivation depends on both the E_m and the intracellular Ca^{2+} concentration (typically 100 to 200 milliseconds at -80 mV and low intracellular Ca^{2+} concentration). This means that I_{CaL} must recover from inactivation between action potentials. As a result, excitability in

Fig. 1.5 Excitability as a Function of Latency. The changes in action potential amplitude and shape of the upstroke as action potentials are initiated at different stages of the relative refractory period of the preceding excitation. (Redrawn from Rosen MS, Wit AL, Hoffman BF. Electrophysiology and pharmacology of cardiac arrhythmias. I. Cellular electrophysiology of the mammalian heart. *Am Heart J*. 1974;88:380.)

pacemaking cells may not be recovered by the end of phase 3 of the action potential and full restoration of maximum diastolic potential because L-type Ca^{2+} channels require longer time to recovery from inactivation to be able to mediate the upstroke of a new action potential. In other words, sinus and AV nodal cells remain refractory for a time interval that is longer than the time it takes for full membrane repolarization to occur, a phenomenon termed *postrepolarization refractoriness*. This can also occur in working myocardium during some disease states such as myocardial infarction.

PROPAGATION

Cardiac excitation involves generation of the action potential by individual cells, followed by propagation of the electrical impulse along the cardiac muscle fiber and rapidly from cell to cell throughout the cardiac tissue. Conduction velocity refers to the speed of propagation of the action potential through cardiac tissue. The conduction velocity varies in cardiac tissues, ranging from 0.05 m/s in the atrioventricular node (AVN), to 0.5 m/s in atrial and ventricular working myocardium, 2 m/s in the bundle branches, and up to 4 m/s in Purkinje fibers.²⁰ In most regions of the heart, conduction does not occur as a continuous process; rather, the propagating electrical wavefronts interact with structural boundaries that exist at the cellular level (cell membranes, intercellular gap junctions, the three-dimensional [3-D] arrangement of cardiomyocytes), as well as at the more macroscopic level (microvasculature, connective tissue barriers, trabeculation).^{21,22}

Intracellular Propagation

Once initiated, the action potential propagates along the cell membrane until the entire cardiomyocyte is depolarized. The velocity of propagation increases with increasing cell diameter, action potential amplitude, and the initial rate of the rise of the action potential.

An action potential traveling along a cardiac muscle fiber is propagated by local circuit currents, much as it does in nerve and skeletal muscle. Conduction velocity along the cardiac fiber is directly related to the action potential amplitude (i.e., the voltage difference between the fully depolarized and the fully polarized regions) and the rate of change of potential (i.e., the rate of rise of phase 0 of the action potential

[dV/dt]). These factors depend on the amplitude of I_{Na} , which, in turn, is directly related to the E_m at the time of stimulation, the availability of Na^+ channels for stimulation, and the size of the Na^+ electrochemical potential gradient across the cell membrane.

Normally, the charge flow across depolarizing ion channels (I_{Na}) is significantly larger than the charge needed to excite the same cell, providing sufficient extra stimulatory current to drive propagation forward. This property (referred to as “propagation reserve” or “safety of propagation”) helps to maintain action potential propagation under different physiological and pathophysiological conditions.²³ Working atrial and ventricular myocardium and, in particular, Purkinje fibers have high concentrations of Na^+ channels (Purkinje fibers contain up to 1 million Na^+ channels per cell), which help to generate a large depolarizing current flow (I_{Na}) during the action potential. The large I_{Na} spreads quickly within and between cells to support rapid conduction.

Reduction of membrane excitability leads to a reduction in the rate or amplitude of depolarization (I_{Na}) during phase 0 of the action potential. Conduction velocity decreases monotonically with progressive reduction of membrane excitability. When the safety factor for conduction falls to less than 1 (i.e., the source current becomes less than the current necessary for excitation of downstream tissue), conduction can no longer be sustained, and failure (conduction block) occurs.

In tissues with slow response action potentials (sinus and AV nodes), the upstroke of the action potential is formed by I_{CaL} instead of I_{Na} . Because I_{CaL} has lower amplitude and slower activation kinetics than I_{Na} , slow response action potentials exhibit reduced amplitudes and upstroke velocities. Hence slow conduction (approximately 0.1 to 0.2 m/s) and prolonged refractoriness are characteristic features of nodal tissues. These cells also have a reduced safety factor for conduction, which means that the stimulating efficacy of the propagating impulse is low, and conduction block occurs easily.

Intercellular Propagation

Propagation of action potentials from one cell to adjacent cells is achieved by direct ionic current spread (without electrochemical synapses) via specialized, low resistance intercellular connections (gap junctional channels) located mainly in arrays within the intercalated disks. Gap junctions facilitate impulse propagation throughout the heart, so that the heart behaves electrically as a functional syncytium, resulting in a coordinated mechanical function.²²

Gap junctional channels connect neighboring cells and allow biochemical and low-resistance electrical coupling. Although the resistivity of the gap junctional membrane for the passage of ions and small molecules and for electrical propagation is several orders of magnitude lower compared with uncoupled cell membranes, gap junction coupling provides a resistance pathway that is several orders of magnitude higher than the cytoplasmic intracellular resistivity (conduction delay is approximately 0.21 to 0.27 milliseconds at gap junctions, and 0.05 to 0.1 milliseconds at the cell membrane).²⁴ As a consequence, impulse propagation along single cell chains of cardiomyocytes is saltatory, in which the high-resistance intercellular junctions alternate with the low cytoplasmic resistance. However, this feature is lost in intact multicellular tissue due to lateral gap junctional coupling which serves to average local small differences in activation times of individual cardiomyocytes at the excitation wavefront.¹⁹

The number, size, and molecular composition of the gap junction channels contribute to the specific propagation properties of a given tissue. Tissue-specific connexin expression and gap junction spatial distribution, as well as the variation in the structural composition of gap junction channels, allow for a greater versatility of gap junction physiological features and enable disparate conduction properties in cardiac tissue.²⁵

Three different connexins are prominently expressed in the atrial and ventricular myocardium: connexin 40 (Cx40), connexin 43 (Cx43), and connexin 45 (Cx45), named for their molecular masses. A fourth connexin has been described in the AVN (Cx31.9). Cx40 gap junction channels exhibit the largest conductance and Cx45 the smallest. The myocytes of the sinus node and AVN are equipped with small, sparse, and dispersed gap junctions containing Cx45, a connexin that forms low conductance channels, thus underlying the relatively poor intercellular coupling in nodal tissues, a property that is linked to slowing of conduction. In contrast, atrial myocardium gap junctions consist mainly of Cx43 and Cx40, ventricular myocardium of Cx43, and the Purkinje fibers of Cx40.^{24,25}

Importantly, there is a high redundancy in connexin expression in the heart with regard to conduction of electrical impulse, and a large reduction of intercellular coupling is required to cause major slowing of conduction velocity. It has been shown that a 50% reduction in Cx43 does not alter ventricular impulse conduction. Cx43 expression must decrease by 90% to affect conduction, but even then conduction velocity is reduced only by 20%.^{25,26}

Similar to its behavior during reduced membrane excitability, conduction velocity decreases monotonically with reduction in intercellular coupling. Of note, partial gap junctional uncoupling was shown to result in conduction velocities that are over an order of magnitude slower than those obtained during a maximal reduction of excitability before conduction failure develops.^{19,23}

An alternative to the generally accepted understanding of gap junction-mediated intercellular impulse propagation is the electric field mechanism (also referred to as “ephaptic transmission”). Electrical field coupling (ephaptic coupling) refers to the initiation of an action potential in a nonactivated downstream cell by the electrical field caused by an activated upstream cell. This model postulates that activation spreads along tracts of cardiac cells in a saltatory fashion driven by the negative potential that develops in the restricted cleft space between cells when an action potential develops in the prejunctional membrane. The large I_{Na} in the proximal side of an intercellular cleft at the intercalated disks (where Na^+ channels are concentrated) generates a negative extracellular potential within the cleft, which depolarizes the distal membrane and activates its Na^+ channels. Thus propagation can continue downstream in the absence of gap junctions, provided there is a large I_{Na} at the intercalated disk and a narrow (2 to 5 nm) intercellular cleft that separates the two opposing cells. Computer simulation studies suggest that, under certain conditions, ephaptic coupling may play a role in cardiac impulse propagation, and that ephaptic transmission can explain the insensitivity of conduction velocity to reduced intercellular gap junction coupling. However, the importance and contribution of ephaptic transmission to action potential propagation in normal cardiac tissue are currently unclear and remain difficult to define.^{22,24,25}

Anisotropic Conduction

Anisotropy refers to directionally dependent conduction velocity. Isotropic conduction is uniform in all directions; anisotropic conduction is not. Anisotropy is a normal feature of heart muscle and is related to the differences in longitudinal and transverse conduction velocities, which are attributable to the lower resistivity of myocardium in the longitudinal (parallel to the long axis of the myocardial fiber bundles) versus the transverse direction (eFig. 1.1).²⁵

In normal adult working myocardium, a given cardiomyocyte is electrically coupled to an average of approximately 11 adjacent cells, with gap junctions being predominantly localized at the intercalated discs at the ends of the rod-shaped cells. Lateral (side-to-side) gap junctions in nondisc lateral membranes of cardiomyocytes are much less abundant and occur more often in atrial than ventricular tissues.

This particular subcellular distribution of gap junctions is a main determinant of anisotropic conduction in the heart; a wavefront must traverse more cells in the transverse direction than over an equivalent distance in the longitudinal direction because cell diameter is much smaller than cell length. In addition, less intercellular gap junctional coupling occurs and hence greater resistance and slower conduction transversely than longitudinally.^{19,24}

A further level of anisotropy exists in the normal working myocardium secondary to discontinuities of 3-D myocyte architecture at the tissue scale. The myocardium is not a continuum. Distinct layers or bundles of myocytes are evident in the atria and ventricles, at dimensions ranging from approximately 100 μ m to several millimeters.²² The myocardial tissue is not uniformly connected transverse to the myofiber direction. Ventricular myocytes are arranged in layers four to six cells thick (referred to as sheets, myolaminae, or sheetlets) that are separated by clefts of connective tissue, across which there is little direct cell-to-cell coupling. These layers form a branching network. In addition to the laminar myocyte architecture, transmural myofiber rotation adds further complexity to cellular organization. In a normal heart, myocardial fiber direction changes (gradually) from the endocardium to the epicardium by nearly 90 degrees. A lower axial resistivity in the longitudinal myofiber and myolaminar orientation than in the transverse direction further exacerbates electrical anisotropy.²²

Source-Sink Relationship

Source-sink relationships reflect the interplay between the main factors influencing source current (the rate of rise of the upstroke and amplitude of the action potential) and those that influence the current requirements of the sink (the membrane resistance, the difference between the resting and threshold potentials, cell-to-cell coupling, and tissue geometry).

During action potential propagation, an excited cell serves as a source of electrical charge for depolarizing neighboring unexcited cells. The requirements of adjacent resting cells to reach the threshold E_m constitute an electrical sink (load) for the excited cell. For propagation to succeed, the excited cell must provide sufficient charge to bring the E_m at a site in the sink from its diastolic value to the threshold. Once threshold is reached and an action potential is generated, the load on the excited cell is removed, and the newly excited cell switches from being a sink to being a source for the downstream tissue, thus perpetuating the process of action potential propagation. Action potentials are “regenerative” because they can be conducted over large distances without attenuation. Propagation will continue to be successful as long as the active sources can generate enough current to satisfy local sinks. Alternatively, if the sink overwhelms the source, propagation will fail.²⁷

The current provided by the source must reach the sink. The pathway between the source and the sink includes intracellular resistance (provided by the cytoplasm) and intercellular resistance (provided by the gap junctions). Extracellular resistance plays a role, but it can often be neglected. The coupling resistance is mainly determined by resistance of the gap junctions. Therefore the number and distribution of gap junctions, as well as the conductance of the gap junction proteins (connexins) and the geometry of the source-sink relationship, are important factors for propagation of the action potential.^{21,28}

A major cause for source-sink mismatch is an abrupt change in the structure of the cellular network, such as that which occurs at the Purkinje fiber-ventricular muscle junction. Each Purkinje fiber (source) transfers the impulse to hundreds or thousands of ventricular cardiomyocytes (sink). This mismatch can potentially result in dispersion of the source current to many neighboring cells (sink), and in each of these the accumulated charge may be too low to trigger an action potential, leading to conduction failure.^{12,29} Nonetheless, in a

eFig. 1.1 Anisotropic Conduction. Progression of activation wavefronts in blocks of ventricular myocardium with longitudinal fiber orientation are shown. A wavefront stimulated (*asterisk*) at the left edge progresses more rapidly (wider isochrone spacing, [A]) than one starting perpendicularly (B) because of more favorable conduction parameters in the former direction.

normal heart, the local structure of the cellular network and abrupt changes in geometric properties are not of magnitude to provide sufficient sink-source mismatch and cause conduction block of the normal action potential because the safety factor for conduction is large (i.e., there is a large excess of activating current over the amount required for propagation). However, when the action potential is abnormal, the unexcited area has decreased excitability (e.g., in the setting of acute ischemia), or both, anatomical impediments can result in conduction block.^{19,30}

Reduction of intercellular coupling can improve the safety of propagation despite the presence of significant source-sink mismatch. For example, this is realized in the sinus node, where a small current source (sinus node) meets a large sink (atrium). At the sinus node/atrium border, there is only little expression of connexins, which protects the excitatory current generated in the sinus node from downstream dissipation.²⁴

Importantly, such tissue structures can exhibit directional asymmetry in source-sink relationships. The source is smaller than the sink in the orthodromic direction but larger than the sink in the opposite direction. Depending on the size of the source-sink mismatch, this results in either local conduction delay or conduction block at the junction during orthodromic conduction.^{27,31,32}

Furthermore, the shape of the wavefront is a major determinant of efficiency of propagation. Due to source-sink balance, conduction velocity is dependent on wave curvature (Fig. 1.6). A convex wavefront, as might be observed after point stimulation, has a smaller source and a larger sink because the local excitatory current supplied by the cells in the front of a convex wave diverges into a larger membrane area downstream. Conversely, a concave activation front produces a source-sink mismatch that favors the source, resulting in a high safety factor and more rapid impulse transmission. Hence, as wavefront curvature increases, conduction velocity decreases.^{24,33}

Safety Factor for Conduction

The safety factor for conduction predicts the success of action potential propagation and is based on the source-sink relationship. The *safety factor* is defined as the ratio of the current generated by the depolarizing ion channels of a cell (source) to the current consumed during the excitation cycle of a single cell in the tissue (sink). Thus the safety factor

Fig. 1.6 Wave Curvature and Source-Sink Balance. (A) Flat wavefronts have source-sink balance, whereas (B) convex wavefronts have a smaller source and a larger sink. (C) The curvature of a spiral wave increases as one moves along the wavefront toward the spiral center (the curvature at point 3 is greater than at point 2, which is greater than at point 1). At the innermost aspect of the wavefront, the source is too small to excite the adjacent sink; the result is a core of unexcited cells around which rotation occurs. Color bar indicates percentage depolarization; gray indicates subthreshold voltage. (From Spector P. Principles of cardiac electric propagation and their implications for re-entrant arrhythmias. *Circ Arrhythmia Electrophysiol.* 2013;6:655–661.)

for propagation is proportional to the excess of source current over the sink needs. By this definition, conduction fails when the safety factor drops to less than 1 and becomes increasingly stable as it rises to more than 1.

Membrane excitability, intercellular coupling, and tissue structure have a huge influence on the safety of propagation. The safety factor decreases monotonically as membrane excitability is reduced. In addition, the safety factor tends to be low for propagation that occurs from a smaller cell to a larger cell or from a relatively small number of cells to a larger number of cells.

On the other hand, although reduction of intercellular coupling between the source cell and the sink leads to slowing of conduction, it is associated with improved safety of conduction. Uncoupling the source cells from neighboring cells prevents the source from becoming overwhelmed by sink demand. As cells become less coupled, there is greater confinement of depolarizing current to the depolarizing source cell, with less electrotonic load and axial flow of charge to the downstream “sink” cells. As a result, individual cells depolarize with a high margin of safety, but conduction proceeds with long intercellular delays. At such low levels of coupling, conduction is very slow but, paradoxically, very robust. Due to the high safety factor, extremely slow conduction velocities can be sustained in tissue with greatly reduced intercellular coupling.^{25,27,31,34}

EXCITATION-CONTRACTION COUPLING

Excitation-contraction coupling describes the physiological process by which electrical stimulation of the cardiomyocytes (the action potential) results in a mechanical response (muscle contraction). The contraction of a cardiac myocyte is governed primarily by intracellular Ca^{2+} concentration (Fig. 1.7). Ca^{2+} enters the cell during the plateau phase of the action potential through the L-type Ca^{2+} channels that line areas of specialized invaginations known as transverse (T) tubules. Although the rise in intracellular Ca^{2+} is small and not sufficient to induce contraction, the small amount of Ca^{2+} entering the cell via I_{CaL} triggers a massive release of Ca^{2+} from the sarcoplasmic reticulum (the major store for Ca^{2+}) into the cytosol by opening the ryanodine receptor 2 (RyR2) channels (present in the membrane of the sarcoplasmic reticulum) in a process known as *calcium-induced calcium release* (CICR). Approximately 75% of Ca^{2+} present in the cytoplasm during contraction is released from the sarcoplasmic reticulum.

Each junction between the sarcolemma (T tubule) and sarcoplasmic reticulum, where 10 to 25 L-type Ca^{2+} channels and 100 to 200 RyRs are clustered, constitutes a local Ca^{2+} signaling complex (called a “couplon”). When a Ca^{2+} channel opens, local cytosolic Ca^{2+} concentration rises in less than 1 millisecond to 10 to 20 μM in the junctional cleft, and this activates RyR2 to release Ca^{2+} from the sarcoplasmic reticulum. The close proximity of the RyR2 to the T tubule enables each L-type Ca^{2+} channel to activate four to six RyR2s and generate a “ Ca^{2+} spark.” Ca^{2+} influx via I_{CaL} simultaneously activates approximately 10,000 to 20,000 couplons in each ventricular cardiomyocyte with every action potential.³⁵

CICR raises cytosolic Ca^{2+} levels from approximately 10^{-7} M to approximately 10^{-5} M. The free Ca^{2+} binds to troponin C, a component of the thin filament regulatory complex, and thus causes a conformational change in the troponin-tropomyosin complex, such that troponin I exposes a site on the actin molecule that is able to bind to the myosin ATPase located on the myosin head. This binding results in ATP hydrolysis that supplies energy for a conformational change to occur in the actin-myosin complex. The result of these changes is a movement (ratcheting) between the myosin heads and the actin, such that the actin and myosin filaments slide past each other and thereby shorten

the sarcomere length. Ratcheting cycles continue to occur as long as cytosolic Ca^{2+} levels remain elevated.

CICR typically induces release of approximately 50% to 60% of sarcoplasmic reticulum Ca^{2+} content. RyR2 channels are inactivated by a feedback mechanism from the rising Ca^{2+} concentration in the cleft and, more importantly, by the decline of sarcoplasmic reticulum Ca^{2+} content (a process referred to as luminal Ca^{2+} -dependent deactivation). This process ensures that the sarcoplasmic reticulum never is fully depleted of Ca^{2+} physiologically.

Relaxation requires the removal of Ca^{2+} from the cytosol, a process vital for enabling cardiac chamber relaxation and filling, as well as for prevention of arrhythmias. At the end of phase 2 of the action potential, Ca^{2+} entry into the cell slows, and most of the surplus Ca^{2+} in the cytosol is resequenced into the sarcoplasmic reticulum by the SERCA, the activity of which is controlled by the phosphoprotein phospholamban. In addition, some of the Ca^{2+} is extruded from the cell by the sarcolemmal $\text{Na}^{+}\text{-Ca}^{2+}$ exchanger and, to a minor degree, the cell membrane Ca^{2+} ATPase, to balance the Ca^{2+} that enters the cell via I_{CaL} . As the cytosolic Ca^{2+} concentration drops, Ca^{2+} dissociates rapidly from the myofilaments, thus inducing a conformational change in the troponin complex leading to troponin I inhibition of the actin binding site. At the end of the cycle, a new ATP binds to the myosin head and displaces the adenosine diphosphate, and the initial sarcomere length is restored, thus ending contraction. Recurring Ca^{2+} release-uptake cycles provide the basis for periodic elevations of cytosolic Ca^{2+} concentration and contractions of myocytes, hence for the orderly beating of the heart.

Ion channels are pore-forming membrane proteins that regulate the flow of ions passively down their electrochemical gradient across the membrane. Ion channels are present on all membranes of cells (plasma membrane) and intracellular organelles (nucleus, mitochondria, endoplasmic reticulum). There are more than 300 types of ion channels in a living cell. The channels are not randomly distributed in the membrane but tend to cluster at the intercalated disc in association with modulatory subunits.

Ion channels are distinguished by two important characteristics: ion permeation selectivity and gating kinetics. Ion channels can be classified by the strongest permeant ion (sodium [Na^+], potassium [K^+], calcium [Ca^{2+}], and chloride [Cl^-]), but some channels are less selective or are not selective, as in gap junctional channels. Size, valency, and hydration energy are important determinants of selectivity. Na^+ channels have a selectivity ratio for Na^+ to K^+ of 12:1. Voltage-gated K^+ and Na^+ channels exhibit more than 10-fold discrimination against other monovalent and divalent cations, and voltage-gated Ca^{2+} channels exhibit more than 1000-fold discrimination against Na^+ and K^+ ions and are impermeable to anions. Ions move through the channel pore at a very high rate (more than 10^6 ions/s).

Gating is the mechanism of opening and closing of ion channels and represents time-dependent transitions among distinct conformational states of the channel protein resulting from molecular movements, most commonly in response to variations in voltage gradient across the plasma membrane (termed voltage-dependent gating) and, less commonly, in response to specific ligand molecules binding to the extracellular or intracellular side of the channel (ligand-dependent gating) or in response to mechanical stress such as stretch, pressure, shear, or displacement (mechanosensitive gating).

Importantly, channel opening and closing are not instantaneous but usually take time. The transition from the resting (closed) state to the open state is called activation. Once opened, channels do not remain in the open state, but instead they undergo conformational transition in a time-dependent manner to a stable nonconducting (inactivated) state. Inactivated channels are incapable of reopening and must undergo recovery or reactivation process back to the resting state to regain their ability to open. Inactivation curves of the various voltage-gated ion channel types differ in their slopes and midpoints of inactivation and can overlap, in which case a steady-state or noninactivating current flows.

Fig. 2.1 The Sodium Channel Macromolecular Complex. See text for discussion. (From Boussy T, Paparella G, de Asmundis C, et al. Genetic basis of ventricular arrhythmias. *Heart Fail Clin.* 2010;6:249–266.)

Ion channels differ with respect to the number of subunits of which they are composed and other aspects of structure. Many ion channels function as part of macromolecular complexes in which many components are assembled at specific sites within the membrane. For most ion channels, the pore-forming subunit is called the α subunit, whereas the auxiliary subunits are denoted β , γ , and so on. Most ion channels have a single pore; however, some have two.

It is important to note that although cardiomyocytes generally last the entire human lifetime, the half-lives of ion channels at the membrane are on the order of hours. The life cycle of cardiac ion channels encompasses many processes, starting from DNA transcription to translation into proteins, protein modification, protein oligomerization, channel transport to specific subdomains of the cell membrane (a process known as forward trafficking), and finally internalization for degradation or recycling (i.e., retrograde trafficking). Given the quick turnover of channels, the intracellular forward trafficking of channels constitutes a key regulatory step in controlling the current density of specific channels and offers targets for therapeutic manipulation of channel function in the treatment of heart disease. In addition, genetic channelopathies can result not only from mutations affecting channel structure and function but also from mutations leading to perturbation of any of the molecular processes involved in channel trafficking.

SODIUM CHANNELS

Structure and Physiology

The cardiac Na^+ channel complex is composed of a primary α and multiple ancillary β subunits. The approximately 2000-amino-acid α subunit contains the channel's ion-conducting pore and controls channel selectivity for Na^+ ions and voltage-dependent gating machinery. This subunit contains all the drug and toxin interaction sites identified to date.

Nine genes encode the α subunit of the Na^+ channel in humans ($\text{Na}_v1.1$ through $\text{Na}_v1.9$). $\text{Na}_v1.5$ is the principal cardiac isoform. $\text{Na}_v1.8$

and $\text{Na}_v1.9$ are primarily expressed peripheral sensory neurons, $\text{Na}_v1.4$ in skeletal muscle, and $\text{Na}_v1.6$ in the central nervous system.

$\text{Na}_v1.5$, encoded by the *SCN5A* gene, consists of four internally homologous domains (I to IV) that are connected to each other by cytoplasmic linkers (Fig. 2.1). Each domain consists of six membrane-spanning segments (S1 to S6), connected to each other by alternating intracellular and extracellular peptide loops. The four domains are arranged in a fourfold circular symmetry to form the channel. The extracellular loops between S5 and S6 (termed the P segments) have a unique primary structure in each domain (Fig. 2.2). The P segments curve back into the membrane to form an ion-conducting central pore whose structural constituents determine the selectivity and conductance properties of the Na^+ channel.¹

Four auxiliary β subunits ($\text{Na}_v\beta1$ to $\text{Na}_v\beta4$, encoded by the genes *SCN1B* to *SCN4B*, respectively) have been identified; each is a glycoprotein with a single membrane-spanning segment. The β subunits modulate density, kinetics, voltage dependence of activation and inactivation, as well as surface expression of the Na^+ channel.¹

Na^+ channels are the typical example of voltage-gated ion channels. Na^+ channels switch among three functional states: deactivated (closed), activated (open), and inactivated (closed), depending on the membrane potential (E_m). These channel states control Na^+ ion permeability through the channel into the cardiomyocyte. Na^+ channel activation allows Na^+ ion influx into the cell, and inactivation blocks the entry of Na^+ ions.

On excitation of the cardiomyocyte by electrical stimuli from adjacent cells, its resting E_m (approximately -85 mV) depolarizes. The positively charged S4 segment of each domain of the α subunit functions as the sensor of the transmembrane voltage; these segments are believed to undergo rapid structural conformational changes in response to membrane depolarization, thus leading to channel opening (activation) from its resting (closed) state and enabling a large and rapid influx of Na^+ (inward Na^+ current, I_{Na}) during the rapid upstroke (phase 0) of the action potential in atrial, ventricular, and Purkinje cardiomyocytes.²

Fig. 2.2 Transmembrane Organization of Sodium Channel Subunits. The primary structures of the subunits of the voltage-gated ion channels are illustrated as transmembrane folding diagrams. Cylinders represent probable α -helical segments: S1 to S3, blue; S4, green; S5, orange; S6, purple; outer pore loop, shaded orange area. Bold lines represent the polypeptide chains of each subunit, with length approximately proportional to the number of amino acid residues in the brain sodium channel subtypes. The extracellular domains of the β 1 and β 2 subunits are shown as immunoglobulin-like folds. ψ shows sites of probable N-linked glycosylation. P represents sites of demonstrated protein phosphorylation by protein kinase A (red circles) and protein kinase C (red diamonds); h in the blue circle signifies an inactivation particle in the inactivation gate loop; the empty blue circles represent sites implicated in forming the inactivation gate receptor. The structure of the extracellular domain of the β subunits is illustrated as an immunoglobulin-like fold based on amino acid sequence homology to the myelin P0 protein. Sites of binding of α and β scorpion toxins (α -ScTx, β -ScTx) and a site of interaction between α and β 1 subunits also are shown. H_3N and NH_3 , Ammonia. (From Caterall WA, Maier SK. Voltage-gated sodium channels and electrical excitability of the heart. In Zipes DP, Jalife J, eds. *Cardiac Electrophysiology: From Cell to Bedside*. 5th ed. Philadelphia: Saunders; 2009:9–17.)

Normally, activation of Na^+ channels is transient; fast inactivation (closing of the pore) starts simultaneously with activation, but because inactivation is slightly slower than activation, the channels remain transiently open to conduct I_{Na} during phase 0 of the action potential before it closes. Each Na^+ channel opens very briefly (less than 1 millisecond) during phase 0 of the action potential; collectively, activation of the channels lasts a few milliseconds and is followed by fast inactivation.

Na^+ channel inactivation comprises different conformational states, including fast, intermediate, and slow inactivation. Fast inactivation is at least partly mediated by rapid occlusion of the inner mouth of the pore by the cytoplasmic interdomain linker between domains III and IV of the α subunit, which has a triplet of hydrophobic residues that likely functions as a hinged “latch” that limits or restricts Na^+ ions from passing through the pore. The carboxyl terminus (C-terminus) also plays an important role in the control of Na^+ channel inactivation and stabilizing the channels in the inactivated state by interacting with the loop linking domains III and IV. Of note, although most Na^+ channels open before inactivating, some actually inactivate without ever opening (a process known as closed-state inactivation).

Once inactivated, Na^+ channels do not conduct any more current and cannot be reactivated (reopened) until after recovery from inactivation. The recovery of the Na^+ channel to reopen is voltage dependent. Channel inactivation is removed when the E_m of the cell repolarizes during phase 4 of the action potential. The recovery of channels from inactivation is also time dependent; Na^+ channels typically activate

within 0.2 to 0.3 milliseconds and inactivate completely within 2 to 5 milliseconds.

Following recovery, Na^+ channels enter a closed state that represents a nonconducting conformation, which allows the channels to be activated again during the next action potential. The fraction of channels available for opening varies from almost 100% at a membrane potential of -90 mV and 50% at an E_m of -75 mV to almost 0% at $+40$ mV. Consequently, highly polarized (-80 to -90 mV) cell membranes can be depolarized rapidly by stimuli because more Na^+ channels reopen, whereas partially depolarized cells with potentials close to threshold -70 mV generate a much slower upstroke because of the inactivation of a proportion of Na^+ channels. Given that Na^+ channels are major determinants of conduction velocity, this velocity generally slows at a reduced E_m .

Na^+ channel activation, inactivation, and recovery from inactivation occur within a few milliseconds. At the end of phase 1 of the action potential, more than 99% of Na^+ channels transit from an open (activated) state to an inactivated state. However, very few Na^+ channels are not inactivated and may reactivate (reopen) during phase 3 of the action potential. The small current produced by these channels (less than 1% of the peak I_{Na}) is called the “window current” because it arises when the sarcolemma reaches a potential that is depolarized sufficiently to reactivate some channels, but not enough to cause complete inactivation. The voltage range for the window current is very restricted and narrow in healthy hearts, thus granting it a small role during the cardiac action potential.

In addition to these rapid gating transitions, Na^+ channels are also susceptible to slower inactivating processes (slow inactivation) if the membrane remains depolarized for a longer time. These slower events can contribute to the availability of active channels under various physiological conditions. Whereas fast-inactivated Na^+ channels recover rapidly (within 10 milliseconds) during the hyperpolarized interval between stimuli, slow inactivation requires much longer recovery times (ranging from hundreds of milliseconds to many seconds). The molecular movements leading to slow inactivation are less well understood. The P segments seem to play a key role in slow inactivation.

Some Na^+ channels occasionally show alternative gating modes consisting of isolated brief openings occurring after variable and prolonged latencies and bursts of openings, during which the channel opens repetitively for hundreds of milliseconds. The isolated brief openings are the result of occasional failure of inactivation. Prolonged opening or reopening of some Na^+ channels during phases 2 and 3 can result in a small late Na^+ current (I_{NaL}). Despite its minor contribution in healthy hearts, I_{NaL} can potentially play an important role in diseased hearts.³

Function

Na^+ channels play a pivotal role in the initiation, propagation, and maintenance of the normal cardiac rhythm. The I_{Na} determines excitability and conduction in atrial, His-Purkinje system (HPS), and ventricular myocardium. On membrane depolarization, the voltage-gated Na^+ channels respond within a millisecond by opening, thus leading to the very rapid depolarization of the cardiac cell membrane (phase 0 of the action potential), reflected by the fast (within tenths of a microsecond) subsequent opening of Na^+ channels triggering the excitation-contraction coupling. Na^+ entry during phase 0 of the action potential also modulates intracellular Na^+ levels and, through Na^+ - Ca^{2+} exchange, intracellular Ca^{2+} concentration and cell contraction.

Na^+ channel also plays a crucial role in the propagation of action potentials throughout the atrium, HPS, and ventricles. The opening of Na^+ channels in the atria underlies the P wave on the electrocardiogram (ECG), and in the ventricles I_{Na} underlies the QRS complex and enables a synchronous ventricular contraction. Because the upstroke of the electrical potential primarily determines the speed of conduction between adjacent cells, Na^+ channels are present in abundance in tissues where speed is of importance. Cardiac Purkinje cells contain up to 1 million Na^+ channels, a finding that illustrates the importance of rapid conductance in the heart.

Na^+ channels also make a contribution in the plateau phase (phase 2) and help determine the duration of the action potential. After phase 0 of the action potential, I_{Na} decreases to less than 1% of its peak value over the next several milliseconds because of voltage-dependent inactivation. This persistent or “late” inward I_{Na} (I_{NaL}), along with the L-type Ca^{2+} current (I_{CaL}), helps maintain the action potential plateau.

Furthermore, inactivation of the Na^+ channel is very important, as it prevents cells from being prematurely reexcited. With repolarization, the Na^+ channel normally recovers rapidly from inactivation (within 10 milliseconds) and is ready to open again. Hence Na^+ channels help determine the frequency of action potential firing. To a lesser extent, cardiac Na^+ channels are also present in the sinus node and the atrioventricular node (AVN), where they contribute to pacemaker activity.

Regulation

The regulatory proteins interacting with $\text{Na}_v1.5$ (Fig. 2.3) can be classified as follows: (1) anchoring-adaptor proteins (e.g., ankyrin-G, syntrophin proteins, multicopy suppressor of *gsp1* [MOG1]), which play roles only in trafficking and targeting the channel protein in specific membrane compartments; (2) enzymes interacting with and modifying

the channel structure (posttranslational modifications), such as protein kinases or ubiquitin ligases; and (3) proteins modulating the biophysical properties of $\text{Na}_v1.5$ on binding (e.g., caveolin-3, calmodulin, glycerol 3-phosphate dehydrogenase 1-like [G3PD1L], telethonin, Plakophilin-2). Coexpression of $\text{Na}_v1.5$ with its β subunits induces acceleration in the recovery from inactivation and enhancement of I_{Na} amplitude.⁴

The cardiac Na^+ channels are subject to phosphorylation and dephosphorylation by kinases or phosphatases. The intracellular linker between domains I and II contains eight consensus sites for cyclic adenosine monophosphate (cAMP)-dependent protein kinase A (PKA) phosphorylation. cAMP-dependent PKA and G protein stimulatory α subunit ($\text{Gs}\alpha$) modulate the function of expressed cardiac Na^+ channels on β -adrenergic stimulation and enhance I_{Na} .

In contrast, the activation of α -adrenergic stimulating protein kinase C (PKC) results in the attenuation of I_{Na} . The effect of PKC is largely attributable to phosphorylation of a highly conserved serine in the linker between domains III and IV. PKC reduces the maximal conductance of the channels and alters gating. Na^+ channels exhibit a hyperpolarizing shift in the steady-state availability curve, suggesting an enhancement of inactivation from closed states.

All subunits of the Na^+ channel are modified by glycosylation. The $\beta 1$ and $\beta 2$ subunits are heavily glycosylated, with up to 40% of the mass being carbohydrate. In contrast, the α subunit is only 5% sugar by weight. Sialic acid is a prominent component of the N-linked carbohydrate of the Na^+ channel. The addition of such a highly charged carbohydrate has predictable effects on the voltage dependence of gating through alteration of the surface charge of the channel protein.

Pharmacology

Na^+ channels are the targets for the action of class I antiarrhythmic drugs. Na^+ channel blockers bind to a specific receptor within the channel's pore. The binding blocks ion movement through the pore and stabilizes the inactivated state of Na^+ channels. Blockade of Na^+ channels tends to decrease tissue excitability and conduction velocity (by attenuating peak I_{Na}) and can shorten action potential duration (by attenuating late I_{Na}).

One important component in the action of antiarrhythmic drugs is a voltage-dependent change in the affinity of the drug-binding site (i.e., the channel is a modulated receptor). In addition, restricted access to binding sites can contribute to drug action, a phenomenon that has been called the guarded receptor model. Open and inactivated channels are more susceptible to block than resting channels, likely because of a difference in binding affinity or state-dependent access to the binding site. Consequently, binding of antiarrhythmic drugs occurs primarily during the action potential (known as use-dependent block), and the block dissipates after repolarization (i.e., in the interval between action potentials). When the time interval between depolarizations is insufficient for block to recover before the next depolarization occurs (secondary to either abbreviation of the interval between action potentials during fast heart rates or slow kinetics of the unbinding of the Na^+ channel blocker), block of Na^+ channels accumulates (resulting in an increased number of blocked channels and enhanced blockade). A drug with rapid kinetics produces less channel block with the subsequent depolarization than a drug with slower recovery. Use-dependent block is important for the action of antiarrhythmic drugs because it allows strong drug effects during fast heart rates associated with tachyarrhythmias but limits Na^+ channel block during normal heart rates. This property is known as use-dependence and is seen most frequently with the class IC agents, less frequently with the class IA drugs, and rarely with the class IB agents. Importantly, drug recovery kinetics can potentially be slowed by pathophysiological conditions such as membrane depolarization, ischemia, and acidosis.

Fig. 2.3 Topology of Na_v1.5 and Its Interaction With Various Regulatory Proteins. The pore-forming α subunit of Na_v1.5 consists of four homologous domains (DI to DIV), connected together by intracellular and extracellular loops. Several regulatory proteins for Na_v1.5 are identified and their sites of interaction have been mapped on the α subunit of the Na_v1.5 channel. Many of these interactions are shown to take place at the intracellular loops or the C-terminus of Na_v1.5. For a few proteins that have been shown to associate with Na_v1.5, the sites of interaction on the Na_v1.5 channel are still unknown. *CaMKII*, Ca²⁺-calmodulin-dependent kinase II; *FGF13*, fibroblast growth factor 13; *GPD1-L*, glycerol-3-phosphate dehydrogenase 1-like; *MOG1*, multicopy suppressor of gsp1. (From Shy D, Gillet L, Abriel H. Cardiac sodium channel Na_v1.5 distribution in myocytes via interacting proteins: the multiple pool model. *Biochim Biophys Acta*. 2013;1833: 886–894.)

Class I antiarrhythmic drugs are classified into three groups according to rates of drug binding to and dissociation from the channel receptor. Class IC drugs (flecainide and propafenone) block both the open and inactivated Na⁺ channels (which is induced by membrane depolarization) and have the slowest kinetics of unbinding during diastole. The results are prolongation of conduction at normal heart rates and a further increase in the effect at more rapid rate (use-dependence).

The class IB agents (lidocaine, mexiletine, and tocainide) block both open and inactivated Na⁺ channels and dissociate from the channel more rapidly than other class I drugs. As a consequence, class IB drugs exhibit minimal or no effects on the Na⁺ channels in normal tissue but cause significant conduction slowing in depolarized tissue, especially at faster depolarization rates. Furthermore, class IB drugs are less effective in the atrium, where the action potential duration is so short that the Na⁺ channel is in the inactivated state only briefly compared with the relatively long diastolic recovery times; thus accumulation of block is less likely to result from the rapid recovery of block.

Class IA drugs (quinidine, procainamide, and disopyramide) exhibit open state block, have intermediate effects on Na⁺ channels, and generally only cause significant prolongation of conduction in cardiac tissue at rapid heart rates. Because the open state block is dominant and recovery from block is slow, these drugs are effective in both the atrium (where action potential duration is short) and the ventricle.

Importantly, class IA drugs also have moderate K⁺ channel blocking activity (which tends to slow the rate of repolarization and prolong the action potential duration) and anticholinergic activity, and they tend to depress myocardial contractility. At slower heart rates, when use-

dependent blockade of I_{Na} is not significant, K⁺ channel blockade becomes predominant (reverse use-dependence), leading to prolongation of the action potential duration and QT interval and increased automaticity. Flecainide and propafenone also have K⁺ channel blocking activity and can increase the action potential duration in ventricular myocytes. Propafenone has significant β -adrenergic blocking activity.

The late I_{Na} (I_{NaL}) also can be a target for blockade. Several drugs exhibit relative selectivity for block of I_{NaL} over peak I_{NaS} including mexiletine, flecainide, lidocaine, amiodarone, and ranolazine.

Inherited Channelopathies

Mutations in genes that encode various subunits of the cardiac Na⁺ channel or proteins involved in regulation of the inward I_{Na} have been linked to several types of electrical disorders (Table 2.1). Depending on the mutation, the consequence is either a gain of channel function (with consequent prolongation of action potential duration because more positive ions accumulate in the cell) or an overall loss of channel function that influences the initial depolarizing phase of the action potential (with consequent decrease in cardiac excitability and electrical conduction velocity). It is noteworthy that a single mutation can cause different phenotypes or combinations thereof. The pathophysiology and clinical presentation of those channelopathies are discussed in detail in Chapter 31.⁵

Long QT Syndrome

Type 3 congenital long QT syndrome (LQTS; LQT3), which accounts for approximately 5% to 10% of congenital LQTS cases, is caused by

TABLE 2.1 Inherited Cardiac Sodium Channelopathies

Clinical Phenotype	Gene	Protein	Functional Effect
Long QT Syndrome (LQTS)			
LQT3	SCN5A	Na _v 1.5	↑ late or sustained I _{Na}
LQT9	CAV3	Caveolin-3	↑ sustained I _{Na}
LQT10	SCN4B	Na _v β4	↑ sustained I _{Na}
LQT12	SNTA1	α1-syntrophin	↑ sustained I _{Na}
Brugada Syndrome (BrS)			
BrS1	SCN5A	Na _v 1.5	↓ I _{Na}
BrS2	GPD1L	G3PD1L	↓ I _{Na}
BrS5	SCN1B	Na _v β1	↓ I _{Na}
BrS7	SCN3B	Na _v β3	↓ I _{Na}
BrS11	RANGRF	MOG1, Na _v 1.5 cofactor	↓ I _{Na}
BrS12	SLAMP	Sarcolemmal associated protein	↓ I _{Na}
BrS14	SCN2B	Na _v β2	↓ I _{Na}
BrS15	PKP2	Plakophilin-2	↓ I _{Na}
BrS16	FGF12	Fibroblast growth factor homologous factor-1	↓ I _{Na}
BrS17	SCN10A	Na _v 1.8	↓ I _{Na}
BrS18	HEY2	Transcriptional factor	↑ I _{Na}
Early Repolarization Syndrome (ERS)			
ERS6	SCN5A	Na _v 1.5	↓ I _{Na}
ERS7	SCN10A	Na _v 1.8	↓ I _{Na}
Progressive Cardiac Conduction Disease			
	SCN5A	Na _v 1.5	↓ I _{Na}
	SCN1B	Na _v β3	↓ or ↑ I _{Na}
Congenital Sick Sinus Syndrome			
	SCN5A	Na _v 1.5	↓ I _{Na}
Atrial Standstill			
	SCN5A	Na _v 1.5	↓ I _{Na}
Familial Atrial Fibrillation			
	SCN5A	Na _v 1.5	Different and discordant molecular phenotypes
	SCN1B	Na _v β1	Different and discordant molecular phenotypes
	SCN2B	Na _v β2	Different and discordant molecular phenotypes
Dilated Cardiomyopathy			
	SCN5A	Na _v 1.5	Different and discordant molecular phenotypes
Sudden Infant Death Syndrome			
	SCN5A	Na _v 1.5	↓ I _{Na}
	CAV3	Caveolin-3	↓ I _{Na}
	GPD1L	G3PD1L	↑ late I _{Na}
SCN5A Overlap Syndromes			
	SCN5A	Na _v 1.5	↓ or ↑ I _{Na}

I_{Na}, Sodium current.

gain-of-function mutations in the *SCN5A* gene, which encodes the α subunit of the Na⁺ channel (Na_v1.5), *SCN5A*. More than 200 mutations have been identified in *SCN5A*, with most being missense mutations mainly clustered in Na_v1.5 regions that are involved in fast inactivation (i.e., S4 segment of domain IV, the domain III–domain IV linker, and the cytoplasmic loops between the S4 and S5 segments of domain III and domain IV), or in regions that stabilize fast inactivation (e.g., the C-terminus).⁵

Several mechanisms have been identified to underlie ionic effects of *SCN5A* mutations in LQT3 (see eFigs. 31.1 and 31.2). Most *SCN5A* mutations cause a gain of function through disruption of fast inactivation, thus allowing repeated reopening during sustained depolarization and resulting in an abnormal, small, but functionally important sustained (or persistent) noninactivating Na⁺ current (I_{Na}) during action potential plateau. Because the general membrane conductance is small during the action potential plateau, the presence of a persistent inward I_{Na},

even of small amplitude, can potentially have a major impact on the plateau duration and can be sufficient to prolong repolarization and QT interval. QT prolongation and the risk of developing arrhythmia are more pronounced at slow heart rates, when the action potential duration is longer, thereby allowing more I_{Na} to enter the cell.⁶

Other less common mechanisms of *SCN5A* mutations to cause LQT3 include increased window current, which results from delayed inactivation of mutant Na^+ channels, occurring at more positive potentials and widening the voltage range during which the Na^+ channel may reactivate without inactivation. In addition, some mutations cause slower inactivation, which allows longer channel openings and causes a slowly inactivating I_{Na} . This current is I_{NaL} and is to be distinguished from I_{sus} (which does not inactivate). Comparable to I_{sus} , both the window current and I_{NaL} exert their effects during phases 2 and 3 of the action potential, in which normally no or very little I_{Na} is present. Other mutations induce prolonged action potential duration by enhancing recovery from inactivation, an effect that leads to larger peak I_{Na} by increasing the fraction of channels available for activation (because of faster recovery) during subsequent depolarizations. Finally, some mutations can cause increased expression of mutant $Na_v1.5$ through enhanced messenger RNA (mRNA) translation or protein trafficking to the sarcolemma, decreased protein degradation, or altered modulation by β subunits and regulatory proteins. These effects lead to larger I_{Na} density during phase 0 of the action potential. Importantly, one single *SCN5A* mutation can potentially cause several changes in the expression and/or gating properties of the resulting Na^+ channels.

Regardless of the mechanism, increased Na^+ current (I_{sus} , window current, I_{NaL} , or peak I_{Na}) upsets the balance between depolarizing and repolarizing currents in favor of depolarization. The resulting delay in the repolarization process triggers early afterdepolarizations (EADs) by reactivation of the L-type Ca^{2+} channel during phase 2 or 3 of the action potential, especially in Purkinje fiber myocytes, in which action potential durations are intrinsically longer. Compared with other LQT subtypes, patients with LQT3 are particularly at risk for sudden cardiac death (SCD), and cardiac arrest is often the first clinical event.

LQT9 is caused by gain-of-function mutations on the *CAV3* gene, which encodes caveolin-3, a plasma membrane scaffolding protein that interacts with $Na_v1.5$ and plays a role in compartmentalization and regulation of channel function. Mutations in *CAV3* induce kinetic alterations of the $Na_v1.5$ current that result in persistent Na^+ current (I_{sus}) and have been reported in cases of sudden infant death syndrome (SIDS).

LQT10 is caused by loss-of-function mutations on the *SCN4B* gene, which encodes the β subunit ($Na_v\beta4$) of the $Na_v1.5$ channel. These mutations likely cause a shift in the inactivation of the I_{Na} toward more positive potentials, resulting in increased window currents at an E_m corresponding to phase 3 of the action potential.

LQT12 is caused by mutations on the *SNTA1* gene, which encodes $\alpha1$ syntrophin, a cytoplasmic adaptor protein that enables the interaction among $Na_v1.5$, nitric oxide synthase, and the sarcolemmal Ca^{2+} adenosine triphosphatase (ATPase) complex that appears to regulate ion channel function. By disrupting the interaction between $Na_v1.5$ and the sarcolemmal Ca^{2+} ATPase complex, *SNTA1* mutations cause increased $Na_v1.5$ nitrosylation with consequent reduction of channel inactivation and enhanced I_{sus} densities.

Brugada Syndrome

Brugada syndrome is an autosomal dominant inherited channelopathy characterized by an elevated ST segment or J wave appearing in the right precordial leads. This syndrome is associated with a high incidence of SCD secondary to a rapid polymorphic ventricular tachycardia (VT) or ventricular fibrillation (VF). Approximately 65% of mutations identified in the *SCN5A* gene are associated with the Brugada syndrome

phenotype (Brugada syndrome type 1), and they account for approximately 11% to 28% of cases of Brugada syndrome. So far, more than 300 Brugada syndrome-associated loss-of-function (i.e., reduced peak I_{Na}) mutations have been described in *SCN5A*. Some of these mutations result in loss of function secondary to impaired channel trafficking to the cell membrane (i.e., reduced expression of functional Na^+ channels), disrupted ion conductance (i.e., expression of nonfunctional Na^+ channels), or altered gating function. Altered gating properties comprise delayed activation (i.e., activation at more positive potentials), earlier inactivation (i.e., inactivation at more negative potentials), faster inactivation, and enhanced slow inactivation.^{2,7}

Most of the mutations are missense mutations, whereby a single amino acid is replaced by a different amino acid. Missense mutations commonly alter the gating properties of mutant channels. Because virtually all reported *SCN5A* mutation carriers are heterozygous, mutant channels with altered gating may cause up to a 50% reduction of I_{Na} . Different *SCN5A* mutations can cause different degrees of I_{Na} reduction and therefore different degrees of severity of the clinical phenotype of Brugada syndrome.⁷

In addition to *SCN5A* mutations, reduction in I_{Na} can be caused by mutations in *SCN1B* (encoding the $\beta1$ and $\beta1b$ subunits of the Na^+ channel), *SCN2B* (encoding the $\beta2$ subunit), and *SCN3B* (encoding the $\beta3$ subunit), resulting in the clinical phenotype of Brugada syndrome.⁷ Recently, *SCN10A* (which encodes $Na_v1.8$, a neuronal Na^+ channel that appears to play a role in the heart) was identified as a major susceptibility gene for Brugada syndrome (identified in 16.7% of probands). Loss-of-function mutations in *SCN10A* lead to significant reduction in I_{Na} .⁸

Furthermore, mutations in *GPD1L* (which encodes the protein G3PD1L protein) affect the trafficking of the cardiac Na^+ channel to the cell surface, resulting in reduction of I_{Na} and Brugada syndrome. The Brugada phenotype associated with *GPD1L* mutations is characterized by progressive conduction disease, low sensitivity to procainamide, and a relatively good prognosis.⁸

Mutations in several other genes have been reported to cause reduction in I_{Na} and lead to the Brugada phenotype, including *HEY2* (encoding the transcriptional factor HEY2), *FGF12* (encoding for a fibroblast growth factor homologous factor-1, which exerts modulatory effects on cardiac Na^+ and Ca^{2+} channels), *PKP2* (encoding the desmosomal protein plakophilin-2, a known susceptibility gene for arrhythmogenic right ventricular cardiomyopathy [ARVC]), *RANGRF* (encoding MOG1, a protein known to modulate the Na^+ channel), and *SLMAP* (encoding the sarcolemmal membrane-associated protein, SLMAP, a component of T-tubules and sarcoplasmic reticulum).⁸

Early Repolarization Syndrome

Loss-of-function mutations in the $\alpha1$ subunit of $Na_v1.5$ and $Na_v1.8$ (*SCN5A*, *SCN10A*) have been reported in patients with early repolarization syndrome.^{9,10}

Familial Progressive Cardiac Conduction Disease

Loss-of-function *SCN5A* mutations have been linked to familial forms of progressive cardiac conduction disease (referred to as hereditary Lenègre disease, primary cardiac conduction system disease, and familial AV block). This disease is characterized by slowing of electrical conduction through the atria, AVN, His bundle, Purkinje fibers, and ventricles, accompanied by an age-related degenerative process and fibrosis of the cardiac conduction system, in the absence of structural or systemic disease. It is often reflected by varying degrees of AV block and bundle branch block. Whether the age-dependent fibrosis of the conduction system is a primary degenerative process in progressive cardiac conduction disease or a physiological process that is accelerated by I_{Na} reduction

remains to be established. A single loss-of-function *SCN5A* mutation can cause isolated progressive cardiac conduction disease or can be combined with the Brugada syndrome (overlap syndrome). Loss-of-function mutations in *SCN1B* also have been identified in patients with progressive cardiac conduction disease who carried no mutation in *SCN5A*.

Congenital Sick Sinus Syndrome

Although I_{Na} does not play a prominent role in sinus node activity, mutations in *SCN5A* have been linked to sick sinus syndrome, manifesting as sinus bradycardia, sinus arrest, sinoatrial block, or a combination of these conditions, which can progress to atrial inexcitability (atrial standstill). Loss-of-function *SCN5A* mutations result in reduced peak I_{Na} density, hyperpolarizing shifts in the voltage dependence of steady-state channel availability, and slow recovery from inactivation. These effects likely cause reduced automaticity, decreased excitability, and conduction slowing or block of impulses generated in the sinus node to the surrounding atrial tissue. Sinus node dysfunction can also manifest concomitantly with other phenotypes that are linked to *SCN5A* loss-of-function mutations such as Brugada syndrome and progressive cardiac conduction disorders.¹¹

Familial Atrial Fibrillation

Loss-of-function mutations, gain-of-function mutations, and common polymorphisms on the *SCN5A* gene have been identified in some cases of atrial fibrillation (AF) occurring in young patients with structurally normal hearts. It is speculated that I_{Na} reduction can predispose to AF by slowing the electrical conduction velocity and thereby facilitating reentry. On the other hand, gain-of-function mutations can potentially predispose to AF by increasing atrial excitability. AF can occur in patients with other phenotypes of Na^+ channelopathies, including LQT3, Brugada syndrome, dilated cardiomyopathy, and sinus node dysfunction. Furthermore, mutations in the *SCN1B* gene (encoding the $\beta 1$ subunit of the Na^+ channel) and the *SCN2B* gene (encoding the $\beta 2$ subunit of the Na^+ channel) have been identified in patients with AF, many of whom displayed ECG patterns suggestive of the Brugada syndrome.¹²

Dilated Cardiomyopathy

Some cases of familial dilated cardiomyopathy have been linked to *SCN5A* mutations. Dilated cardiomyopathy-linked *SCN5A* mutations cause diverse loss-of-function and gain-of-function changes in the gating properties, but how such changes evoke contractile dysfunction is not understood. It is speculated that *SCN5A* mutations disrupt the interactions between the mutant Na^+ channels and intracellular (or extracellular) proteins that are essential for normal cardiomyocyte structure and architecture. Notably, dilated cardiomyopathy with *SCN5A* mutations often display atrial or ventricular arrhythmias (including AF, VT, and VF), sinus node dysfunction, AV block, and intraventricular conduction delay.¹³

Sudden Infant Death Syndrome

Gain-of-function mutations in *SCN5A* may be the most prevalent genetic cause of SIDS. *SCN5A* mutations in SIDS commonly increase I_{sus} . Less frequently, loss-of-function mutations in *SCN5A* or *CAV3* and gain-of-function mutations in *GPD1-L* have also been found in infants with SIDS. However, it is possible that in these patients SIDS represents a malignant form of LQT3 or Brugada syndrome that manifests during infancy.¹⁴

Overlap Syndrome

A single *SCN5A* mutation can result in multiple clinical phenotypes and rhythm disturbances within the same family, a phenomenon now

referred to as “cardiac sodium channel overlap syndrome.” Not surprisingly, loss-of-function *SCN5A* mutations have often been associated with overlapping phenotypes of Brugada syndrome, sinus node dysfunction, and progressive cardiac conduction disorders, which all share similar underlying mechanisms that implicate I_{Na} reduction. More surprisingly, some *SCN5A* mutations are associated with both BrS1 (I_{Na} loss-of-function) and LQT3 (I_{Na} gain-of-function). Carriers of these mutants present with BrS1, LQT3, or a mixed ECGs with both ST-segment abnormalities and QT elongation. These mutations are likely associated with altered gating properties in a manner that results in both reduction of the peak I_{Na} and augmentation of the persistent I_{Na} . Furthermore, it is likely that genetic background and clinical and environmental factors play a role in the variable disease expressivity and severity.^{5,15}

Acquired Diseases

In heart failure, peak I_{Na} is reduced (likely secondary to reduced *SCN5A* expression), whereas I_{NaL} is increased (likely because of increased phosphorylation of Na^+ channels). $Na_v1.5$ expression is reduced in the surviving myocytes in the border zone of the myocardial infarct. Importantly, Na^+ channel blockers can increase the risk for SCD in patients with ischemic heart disease, possibly by facilitating the initiation of reentrant excitation waves. In addition, I_{NaL} increases during myocardial ischemia, explaining why I_{NaL} inhibition may be an effective therapy for chronic stable angina. $Na_v1.5$ expression is reduced in response to persistent atrial tachyarrhythmias as part of the “electrical remodeling” process, leading to attenuation of I_{Na} .

Furthermore, mutations in *SCN5A* can predispose affected individuals to acquired LQTS induced by a variety of drugs such as antihistamines or antibiotics. These mutations result in changes in channel activity that exert a significant impact on action potential duration only when combined with drug-induced alteration of other channels.

POTASSIUM CHANNELS

Structure and Physiology

Cardiac K^+ channels are membrane-spanning proteins that allow the passive movement of K^+ ions across the cell membrane along its electrochemical gradient. The ion-conducting or pore-forming subunit is generally referred to as the α subunit. The backbone carbonyl oxygen contributed by tripeptide sequence glycine-tyrosine-glycine plus the side-chain oxygens from threonine in the sequence TXGYG (where X represents a variable residue) is common to the pore of all K^+ channels and constitutes the signature motif for determining K^+ ion selectivity. A gating mechanism controls switching between open-conducting and closed-nonconducting states.

K^+ channels represent the most diverse class of cardiac ion channels (Fig. 2.4). The diversity of K^+ currents in native tissues exceeds the number of K^+ channel genes identified. The explanations for this diversity include alternative splicing of gene products, posttranslational modification, and heterologous assembly of β subunits within the same family and assembly with accessory β subunits that modulate channel properties. Even small differences in channel composition give rise to significant functional diversity.¹⁶

Cardiac K^+ channels can be categorized as voltage-gated (K_v) and ligand-gated channels. In K_v channels, pore opening is coupled to the movement of a voltage sensor within the membrane electric field, and they include the rapidly activating and inactivating transient outward current (I_{to}); the ultrarapid (I_{Kur}), rapid (I_{Kr}), and slow (I_{Ks}) components of the delayed rectifier current; and the inward rectifier current (I_{K1}). In contrast, pore opening in ligand-gated channels is coupled to the binding of an organic molecule, including channels activated by a

Fig. 2.4 Molecular Compositions of Cardiac Potassium (K^+) Channels. Amino termini (N) and carboxyl termini (C) are indicated. (A) Voltage-gated (K_v), inward rectifier (K_{ir}), and two-pore α subunits are integral membrane proteins with six, two, and four membrane-spanning domains, respectively. (B) These α subunits assemble as tetramers or dimers to form K^+ -selective pores. (Modified from Oudit GY, Backx PH. Voltage-regulated potassium channels. In Zipes DP, Jalife J, eds. *Cardiac Electrophysiology: From Cell to Bedside*. 5th ed. Philadelphia: Saunders; 2009:29–42.)

decrease in the intracellular concentration of adenosine triphosphate (K_{ATP}) or by acetylcholine (K_{ACh}). Other classes of K^+ channels respond to different stimuli, including changes in intracellular Ca^{2+} concentration and G proteins.¹⁷

On the basis of the primary amino acid sequence of the α subunit, K^+ channels have been classified into three major families (Table 2.2):

1. Channels containing six transmembrane segments and a single pore. This architecture is typical of K_v channels.
2. Channels containing two transmembrane segments (M1 and M2) and a single pore. This architecture is typical of inward rectifier K^+ (K_{ir}) channels, including K_1 , K_{ATP} , and K_{ACh} channels. These channels conduct K^+ currents more in the inward direction than the outward and play an important role in setting the resting potential close to the equilibrium potential for K^+ and in repolarization. Kir channels form either homotetramers or heterotetramers.
3. Channels containing four transmembrane segments and two pores (K_{2P}). These channels exist as homodimers or heterodimers. K_{2P} currents display little time or voltage dependence.

Each voltage-gated K^+ channel (K_v family) is formed by the coassembly of four identical (homotetramers) or a combination of four different (from the same subfamily, heterotetramers) α subunits ($K_v\alpha$). A total of 38 genes has been cloned and assigned to 12 subfamilies of $K_v\alpha$ (K_v1 to K_v12) on the basis of sequence similarities. Most K_v subfamilies contain many individual channel members (e.g., K_v1 has eight members, identified as $K_v1.1$ to $K_v1.8$, with gene designations *KCNA1* to *KCNA8*, respectively).

Each $K_v\alpha$ contains one domain consisting of six membrane-spanning segments (S1 to S6), connected to each other by alternating intracellular and extracellular peptide loops (similar to one of the four domains of voltage-gated Na^+ and Ca^{2+} channels), with both the amino terminus (N-terminus) and the C-terminus located on the intracellular side of the membrane. The central ion-conducting pore region is formed by the S5 and S6 segments and the S5-S6 linker (P segment); the S5-S6 linker is responsible for K^+ ion selectivity. The S4 segment serves as the voltage sensor.

$K_v\alpha$ can generate voltage-dependent K^+ current when expressed in heterologous systems. However, the assembly of a functional tetramer can occur only in the presence of multiple auxiliary units (see Table 2.2). In many cases, auxiliary subunits coassociate with $K_v\alpha$ and likely modulate cell surface expression, gating kinetics, and drug sensitivity of the α subunit complex. Most K^+ channel β subunits assemble with

α subunits and give rise to an $\alpha\beta_4$ complex. K^+ channel β subunits represent a diverse molecular group, which includes (1) cytoplasmic proteins ($K_v\beta1$ to $K_v\beta4$, $KChIP$, and $KChAP$) that interact with the intracellular domains of $K_v\alpha$; (2) single transmembrane spanning proteins (e.g., $minK$ and $minK$ -related proteins [$MiRPs$]) encoded by the *KCNE* gene family; and (3) large ATP-binding cassette (ABC) transport-related proteins (e.g., the sulfonylurea receptors [$SURs$]).

Similar to voltage-dependent Na^+ (Na_v) and Ca^{2+} (Ca_v) channels, K_v channels typically fluctuate among distinct conformational states because of molecular movements in response to voltage changes across the cell membrane (voltage-dependent gating). The K_v channel activates (opens) on membrane depolarization, thus allowing the rapid passage of K^+ ions across the sarcolemma. After opening, the channel undergoes conformational transition in a time-dependent manner to a stable nonconducting (inactivated) state. Inactivated channels are incapable of reopening, even if the transmembrane voltage is favorable, unless they “recover” from inactivation (i.e., enter the closed state) on membrane repolarization. Closed (preopen) channels are nonconducting but can be activated on membrane depolarization.¹⁸

Four mechanistically distinct types of K_v channel inactivation that are associated with distinct molecular domains have been identified: N-type, C/P-type, AG-type, and U-type. N-type (“ball and chain”) inactivation involves physical occlusion of the intracellular mouth of the channel pore through binding of a small group of amino acids (“inactivation ball tethered to a chain”) at the extreme N-terminus.¹⁸

C/P-type inactivation involves conformational changes in the external mouth of the pore. C/P-type inactivation exists in almost all K^+ channels and may reflect a slow constriction of the pore. This inactivation process is thought to be voltage independent, coupled to channel opening, and is usually slower than N-type inactivation. Recovery from C/P-type inactivation is relatively slow and weakly voltage dependent. Importantly, the rate of C/P-type inactivation and recovery can be strongly influenced by other factors. C/P-type inactivation is strongly accelerated by N-type inactivation, and is promoted by extracellular H^+ ions. Unlike N-type inactivation, C/P-type inactivation is prevented by extracellular K^+ ions binding to the face of the pore. These interactions render C/P-type inactivation an important biophysical process in regulating repetitive electrical activity and determining certain physiological properties such as refractoriness, drug binding, and sensitivity to extracellular ions.

AG-type inactivation involves conformational changes in S4 that inactivate K_v channels directly from the closed (preopen) state. In

addition, some K_v channels also show another type of inactivation (U-type), which exhibits a U-shaped voltage dependence with prolonged stimulation rates. Those channels appear to exhibit preferential inactivation at intermediate depolarizing voltages (corresponding to pre-activated closed state) than at more positive voltages (corresponding to the open state). The exact conformational changes underlying U-type inactivation remain unclear. Importantly, there is extreme diversity in the kinetic and potentially molecular properties of K_v channel inactivation, particularly of C/P-type inactivation.

Function

K^+ channels are a diverse and ubiquitous group of membrane proteins that regulate K^+ ion flow across the cell membrane on the electrochemi-

cal gradient and regulate the resting E_m , the frequency of pacemaker cells, and the shape and duration of the cardiac action potential. Because the concentration of K^+ ions outside the cell membrane is approximately 25-fold lower than that in the intracellular fluid, the opening of K^+ channels generates an outward current resulting from the efflux of positively charged ions that offers a mechanism to counteract, dampen, or restrict the depolarization front (phases 1 through 4 of the action potential) triggered by an influx of cations (Na^+ and Ca^{2+}).

The variation in the level of expression of K^+ channels that participate in the genesis of the cardiac action potential explains the regional differences of the configuration and duration of cardiac action potentials from sinus node and atrial to ventricular myocytes and across the myocardial wall (endocardium, midmyocardium, and epicardium). Moreover, the expression and properties of K^+ channels are not static; heart rate, neurohumoral state, pharmacological agents, cardiovascular diseases (cardiac hypertrophy and failure, myocardial infarction [MI]), and arrhythmias (e.g., AF) can influence those properties, and they underlie the change in action potential configuration in response to variation in heart rate and various physiological and pathological conditions.

Transient Outward Potassium Current

Structure and Physiology

Cardiac I_{to} channels are macromolecular protein complexes, comprising four pore-forming $K_v\alpha$ subunits and a variety of K_v channel accessory (β) subunits (see Fig. 2.4). Two major types of I_{to} have been characterized: (1) I_{to1} generated by voltage-dependent, Ca^{2+} -independent K_v channels; and (2) I_{to2} generated by Ca^{2+} -activated Cl^- channels. In human atrial and ventricular myocytes, the presence of I_{to2} has not been clearly demonstrated.

I_{to1} (which is referred to as I_{to}) displays two phenotypes with distinct recovery kinetics: a rapid or fast I_{to} ($I_{to,fast}$ or $I_{to,f}$) phenotype and a slower phenotype ($I_{to,slow}$ or $I_{to,s}$). The transient nature of I_{to} is secondary to its rapid activation (with time constants of less than 10 milliseconds for both $I_{to,f}$ and $I_{to,s}$) and rapid inactivation (25 to 80 milliseconds for $I_{to,f}$ and 80 to 200 milliseconds for $I_{to,s}$). However, whereas $I_{to,f}$ recovers rapidly from inactivation (60 to 100 milliseconds), $I_{to,s}$ recovers slowly (with time constants on the order of seconds).¹⁷

K_v channels mediating $I_{to,s}$ are formed by the coassembly of four α subunits from the $K_v1.x$ subfamily (primarily $K_v1.4$, and possibly $K_v1.7$), whereas those mediating $I_{to,f}$ are formed by the coassembly of four α subunits from the $K_v4.x$ subfamily (primarily $K_v4.3$, and possibly $K_v4.2$) (see Table 2.2). Among the various accessory subunits identified, a crucial role has been definitively demonstrated only for KChIP2, and potentially for MiRP2.¹⁶

Function

I_{to} is a prominent repolarizing current; it partially repolarizes the membrane, shapes the rapid (phase 1) repolarization of the action potential, and sets the height of the initial plateau (phase 2). Thus the activity of I_{to} channels influences the activation of voltage-gated L-type Ca^{2+} channels and the balance of inward and outward currents during the plateau (mainly the L-type Ca^{2+} current [I_{CaL}] and the delayed rectifier K^+ currents), thereby mediating the duration and the amplitude of phase 2.

The density of I_{to} varies across the myocardial wall and in different regions of the heart. In human ventricles, I_{to} densities are much higher in the epicardium and midmyocardium than in the endocardium. Furthermore, $I_{to,f}$ and $I_{to,s}$ are differentially expressed in the myocardium, thus contributing to regional heterogeneities in action potential waveforms. $I_{to,f}$ is the principal subtype expressed in human atrium. The markedly higher densities of $I_{to,f}$ together with the expression of the ultrarapid delayed rectifier K^+ current, accelerate the early phase of repolarization and lead to lower plateau potentials and shorter action

potentials in atrial as compared with ventricular cells. Due to its slow recovery kinetics, $I_{to,s}$ plays a limited role in repolarization compared to $I_{to,f}$, especially at faster heart rates.¹⁹

Although both $I_{to,f}$ and $I_{to,s}$ are expressed in the ventricle, $I_{to,f}$ is more prominent in the epicardium and midmyocardium (putative M cells) than in the endocardium, whereas $I_{to,s}$ is mainly present in the endocardium and Purkinje fiber cells. These regional differences are responsible for the shorter duration and the prominent phase 1 notch and the “spike-and-dome” morphology of epicardial and midmyocardial compared with endocardial action potentials. A prominent I_{to} -mediated action potential notch in ventricular epicardium but not endocardium produces a transmural voltage gradient during early ventricular repolarization that registers as a J wave or J point elevation on the ECG. I_{to} densities are also reportedly higher in right than in left (midmyocardial and epicardial) ventricular myocytes, consistent with the more pronounced spike-and-dome morphology of right, compared with left, ventricular action potentials, particularly in the epicardium.

Furthermore, variations in cardiac repolarization associated with I_{to} regional differences strongly influence intracellular Ca^{2+} transient by modulating Ca^{2+} entry via the I_{CaL} and Na^+ - Ca^{2+} exchanger, thereby regulating excitation-contraction coupling and regional modulation of myocardial contractility and hence synchronizing the timing of force generation between different ventricular regions and enhancing mechanical efficiency.

Regulation

I_{to} channels are subject to α - and β -adrenergic regulation. α -Adrenergic stimulation reduces I_{to} ; concomitant β -adrenergic stimulation appears to counteract the α -adrenergic effect, at least in part. The effects of α - and β -adrenergic stimulation are exerted by phosphorylation of the $K_v1.4$, $K_v4.2$, and $K_v4.3$ α -subunits by PKA as well as PKC. Calmodulin-dependent kinase II, on the other hand, has been shown to be involved in enhancement of I_{to} . Adrenergic stimulation is also an important determinant of transient outward channel downregulation in cardiac disease. Chronic α -adrenergic stimulation and angiotensin II reduce I_{to} channel expression, which explains channel downregulation in many types of chronic heart disease.

KChIP2, when coexpressed with $K_v4.3$, increases surface channel density and current amplitude, slows channel inactivation, and markedly accelerates the recovery from inactivation. In the ventricle, KChIP2 mRNA is 25-fold more abundant in the epicardium than in the endocardium. This gradient parallels the gradient in I_{to} expression, whereas $K_v4.3$ mRNA is expressed at equal levels across the ventricular wall. Thus transcriptional regulation of the *KChIP2* gene is the primary determinant of I_{to} expression in the ventricular wall.

Observations suggest that MiRP2 is required for the physiological functioning of human $I_{to,f}$ channels and that gain-of-function mutations in MiRP2 predispose to Brugada syndrome through augmentation of $I_{to,f}$.

I_{to} is strongly rate dependent. I_{to} fails to recover from previous inactivation at very fast heart rates; thus tachycardia is associated with reduction of I_{to} , which can be manifest as a decrease in the magnitude of the J wave on the surface ECG. Hence abrupt changes in rate and pauses have important consequences for the early repolarization of the membrane.

I_{to} can be enhanced by aging, low sympathetic activity, high parasympathetic activity, bradycardia, hypothermia, and drugs. Estrogen suppresses the expression of the $K_v4.3$ channel and results in reduced I_{to} and a shallow phase 1 notch.

Phase 1 notch of the action potential modulates the kinetics of slower activating ion currents and consequently the later phases of the action potential. Initial enhancement of phase 1 notch promotes phase 2 dome and delays repolarization, presumably by delaying the peak of

I_{CaL} . However, further enhancement of phase 1 notch prevents the rising of phase 2 dome and abbreviates action potential duration, presumably by deactivation or voltage modulation that reduces I_{CaL} . Thus progressive deepening of phase 1 notch can cause initial enhancement followed by sudden disappearance of phase 2 dome and corresponding prolongation followed by abbreviation of action potential duration. On the other hand, modulators that decrease I_{to} lead to a shift of the plateau phase into the positive range of potentials, thus increasing the activation of the delayed rectifier currents, promoting faster repolarization, and reducing the electrochemical driving force for Ca^{2+} and hence I_{CaL} . Phase 1 notch also affects the function of the Na^+ - Ca^{2+} exchanger and subsequently intracellular Ca^{2+} handling and Na^+ channel function.

Pharmacology

Quinidine, 4-aminopyridine, flecainide, and propafenone produce an open channel blockade and accelerate I_{to} inactivation. Quinidine, but not flecainide or propafenone, produces a frequency-dependent block of I_{to} that results from a slow rate of drug dissociation from the channel. Quinidine has relatively strong I_{to} blocking effect, whereas flecainide mildly blocks I_{to} .

I_{to} blockers can potentially prolong the action potential duration in the atrium and in ischemic ventricular myocardium. However, because the net effects of I_{to} blockade on repolarization depend on secondary changes in other currents, the reduction of I_{to} density can result in a shortening of the ventricular action potential. Moreover, heterogeneous ventricular distribution of I_{to} can cause marked dispersion of repolarization across the ventricular wall that, when accompanied by prominent conduction delays related to Na^+ channel blockade, results in extrasystolic activity through a phase 2 reentrant mechanisms.

Currently no cardioselective and channel-specific I_{to} openers or blockers are available for clinical use. Development of an I_{to} -selective drug is expected to be beneficial in patients with primary abnormality in the I_{to} or in other channels, such as the Brugada syndrome, in which heterogeneity in the expression of I_{to} between epicardium and endocardium in the RV results in the substrate responsible for reentry and ventricular arrhythmias.^{20,21}

Inherited Channelopathies

Gain-of-function mutations in *KCNQ3* (which encodes the α -subunit of the I_{to} channel [$K_v4.3$]) and *KCNE3* (which encodes the auxiliary β subunit [MiRP2]) result in an increase in I_{to} density and cause Brugada syndrome. Furthermore, gain-of-function mutations in *SCN1B* (which encodes the auxiliary $\beta 1$ subunit of the Na^+ channel), in addition to reducing I_{Na} , can also increase I_{to} . Mutations in *SEMA3A* (which encodes semaphorin) were also implicated in Brugada syndrome by increasing I_{to} .⁸

In addition, gain-of-function mutations in *KCNQ3* and *KCNE3* have been linked to familial AF. *KCNE3* mutations were found to increase $I_{to,f}$ and were postulated to cause AF by shortening action potential duration and facilitating atrial reentrant excitation waves (Table 2.3).

A genome-wide haplotype-sharing study associated a haplotype on chromosome 7, harboring DPP6, with idiopathic VF in three distantly related families. Overexpression of *DPP6*, which encodes dipeptidyl-peptidase 6, a putative component of the I_{to} channel complex, was proposed as the likely pathogenetic mechanism. DPP6 significantly alters the inactivation kinetics of both $K_v4.2$ and $K_v4.3$ and promotes expression of these α subunits in the cell membrane.

Importantly, the normally functioning I_{to} channels play an important role in the electrophysiological consequences of the ionic current abnormalities in the Brugada and J wave syndromes. Heterogeneity in the distribution of I_{to} channels across the myocardial wall, being more prominent in ventricular epicardium than endocardium, and particularly

I_{K1} , Inward rectifier K^+ current; I_{KACH} , acetylcholine-activated inward rectifier K^+ current; I_{Kr} , rapidly activating delayed rectifier K^+ current; I_{Ks} , slowly activating delayed rectifier K^+ current; I_{to} , transient outward K^+ current.

in the RV, results in the shorter duration and the prominent phase 1 notch and the spike-and-dome morphology of the epicardial action potential as compared with the endocardium. The resultant transmural voltage gradient during the early phases (phases 1 and 2) of the action potential is thought to be responsible for the inscription of the J wave on the surface ECG. An increase in net repolarizing current, secondary to either a decrease in the inward currents (I_{Na} and I_{CaL}) or an increase in the outward K^+ currents (I_{to} , I_{Kr} , I_{Ks} , acetylcholine-activated potassium current [I_{KACH}], ATP-sensitive potassium current [I_{KATP}]), or both, can

accentuate the action potential notch and lead to augmentation of the J wave or the appearance of ST segment elevation on the surface ECG. An outward shift of currents that extends beyond the action potential notch not only accentuates the J wave but also can lead to partial or complete loss of the dome of the action potential, thus resulting in a protracted transmural voltage gradient that manifests as greater ST segment elevation and gives rise to J wave syndromes. The type of the ion current affected and its regional distribution in the ventricles determine the particular phenotype (including the Brugada syndrome, early repolarization syndrome, hypothermia-induced ST segment elevation, and MI-induced ST segment elevation). The degree of accentuation of the action potential notch leading to loss of the dome depends on the magnitude of I_{to} . These changes are more prominent in regions of the myocardium exhibiting a relatively large I_{to} , such as the RV epicardium; this explains the appearance of coved ST segment elevation, characteristic of Brugada syndrome, in the right precordial ECG leads.¹⁹

In this context, factors that influence the kinetics of I_{to} or the other repolarization currents can modify the manifestation of the J wave on the ECG. Na^+ channel blockers (procainamide, pilsicainide, propafenone, flecainide, and disopyramide), which reduce the inward I_{Na} , can accentuate the J wave and ST segment elevation in patients with concealed J wave syndromes. Quinidine, which inhibits both I_{to} and I_{Na} , reduces the magnitude of the J wave and normalizes ST segment elevation. In addition, acceleration of the heart rate, which is associated with reduction of I_{to} (because of slow recovery of I_{to} from inactivation), results in a decrease in the magnitude of the J wave. Male predominance can potentially result from larger epicardial I_{to} density versus I_{to} in women.

The increased transmural heterogeneity of ventricular repolarization (i.e., dispersion of repolarization between epicardium and endocardium), which is responsible for J point elevation and early repolarization pattern on the surface ECG, is also responsible for the increased vulnerability to ventricular tachyarrhythmias. A significant outward shift in current can cause partial or complete loss of the dome of the action potential in regions where I_{to} is prominent (epicardium), with the consequent loss of activation of I_{CaL} . The dome of the action potential then can propagate from regions where it is preserved (midmyocardium endocardium) to regions where it is lost (epicardium), thus giving rise to phase 2 reentry, which can generate premature ventricular complexes that in turn can initiate polymorphic VT or VF.

Acquired Diseases

An alteration in the expression and distribution of I_{to} is observed in various pathophysiological conditions (eFig. 2.1). Adrenergic effects seem to be involved in at least some of these I_{to} -regulating processes during heart disease.²²

In general, myocardial ischemia, MI, dilated cardiomyopathy, and end-stage heart failure cause downregulation of I_{to} . In fact, I_{to} downregulation is the most consistent ionic current change in the failing heart. The reduction in I_{to} results in attenuation of early repolarization (phase 1) and affects the level of plateau (phase 2) of the action potential and other currents involved in delayed repolarization (phase 3), with resulting prolongation and increased heterogeneity of action potential duration. The prominent epicardial I_{to} contributes to the selective electrical depression of the epicardium. This process leads to the development of a marked dispersion of repolarization between normal and abnormal epicardium and between epicardium and endocardium, which provides the substrate for reentrant arrhythmias and may underlie the increased predisposition to ventricular arrhythmias and SCD in patients with heart failure and ischemic heart disease. In addition, downregulation of I_{to} in advanced heart failure likely slows the time course of force generation, thereby contributing to reduced myocardial performance.

eFig. 2.1 Potassium Channel Remodeling in Heart Disease. Schematic summarizing the principal alterations in the action potential (AP) and corresponding K^+ currents alterations in four situations: heart failure (HF; A), border zone (BZ) of the myocardial infarction (MI; B), atrial fibrillation (AF; C) and pulmonary veins (D). Blue numbers indicate AP phases. Red are changes in pathology (A to C) or differences in pulmonary vein versus atrium (D). Numbers (0 to 4) indicate phases of the action potential. SR, Sarcoplasmic reticulum. (From Algalarrondo V, Nattel S. Potassium channel remodeling in heart disease. *Card Electrophysiol Clin*. 2016;8:337–347.)

On the other hand, compensatory ventricular hypertrophy preceding heart failure is associated with upregulation of I_{to} . The prolongation of the action potential, concomitant with an increase in I_{to} , presumably results from the more negative level of the plateau with less I_{CaL} inactivation and probably less delayed rectifier activation. In contrast, progression of hypertrophy to heart failure is associated with a clear reduction in I_{to} .

Chronic AF reduces atrial I_{to} density and $K_v4.3$ mRNA levels. Hypothyroidism reduces the expression of *KCND2* ($K_v4.2$) genes. In addition, I_{to} may also be reduced and contribute to QT interval prolongation in diabetes. Importantly, with some delay, insulin therapy partially restores I_{to} , possibly by enhancing $K_v4.3$ expression.¹⁹

Ultrarapidly Activating Delayed Outward Rectifying Current

Structure and Physiology

The ion-conducting pore of I_{Kur} channels is formed by four $K_v1.5$ α subunits (encoded by *KCNA5*), whereas the ancillary β subunits $K_v\beta1.2$, $K_v\beta1.3$, and $K_v\beta2.1$ control channel trafficking and plasma membrane integration as well as activation and inactivation kinetics.

I_{Kur} activates rapidly on depolarization in the plateau range and displays outward rectification, but it inactivates very slowly during the time course of the action potential. Inactivation accelerates when $K_v1.5$ is coexpressed with its β subunits.

Function

I_{Kur} is detected only in human atria and not in the ventricles, so that it is the predominant delayed rectifier current responsible for human atrial repolarization and is a basis for the much shorter duration of the action potential in the atrium.

Regulation

β -Adrenergic stimulation enhances I_{Kur} , whereas α -adrenergic stimulation inhibits it, effects likely mediated by PKA and PKC, respectively. Membrane depolarization and elevated extracellular K^+ concentrations reduce $K_v1.5$ expression. In addition, cAMP, mechanical stretch, hyperthyroidism, and dexamethasone increase $K_v1.5$ expression, whereas extracellular acidosis, phenylephrine, and hypothyroidism decrease it.

Coexpression of $K_v\beta1.3$ with $K_v1.5$ induces a fast inactivation and a hyperpolarizing shift in the activation curve (i.e., $K_v\beta1.3$ subunit converts $K_v1.5$ from a delayed rectifier with a modest degree of slow inactivation to a channel with both fast and slow components of inactivation). Data suggest that $K_v\beta1.2$ and $K_v\beta1.3$ subunit modification of $K_v1.5$ currents requires phosphorylation by PKC or a related kinase.

Pharmacology

I_{Kur} is relatively insensitive to class III antiarrhythmic drugs of the methane-sulfonanilide group, but it is highly sensitive to 4-aminopyridine. Selective inhibition of I_{Kur} by 4-aminopyridine prolongs the human atrial action potential duration.

Because I_{Kur} is atrium specific, $K_v1.5$ channels are a promising target for the development of new, safer antiarrhythmic drugs to prevent AF without risk of inducing QT prolongation and ventricular arrhythmias. However, although several selective I_{Kur} blockers have been evaluated, the clinical value of “pure” I_{Kur} blockers for antiarrhythmic therapy in AF remains unproven. Because $K_v1.5$ is downregulated in AF, the beneficial effect of I_{Kur} blockade becomes less certain. Furthermore, because $K_v1.5$ is also expressed in other organs (e.g., brain), discovery of drugs that selectively inhibit cardiac $K_v1.5$ channels remains necessary.¹⁸

Vernakalant, an I_{Kur} blocker, has been shown effective for the acute termination of AF and was approved in Europe. The efficacy of vernakalant in acute cardioversion of AF is likely due to multiple-channel

block. Vernakalant inhibits two atrial-specific K^+ channels (I_{Kur} and I_{KACH}) at low concentration, and is able to block I_{to} and I_{Na} at higher concentration.^{20,23,24}

Although selective I_{Kur} block would be expected to specifically prolong atrial action potential duration, such effects were not observed in healthy subjects at physiological atrial rates. Simulated inhibition of I_{Kur} was shown to increase plateau height, leading to additional activation of I_{Kr} and no net change in action potential duration.

Physiologically, rapid activation of I_{Kur} in the positive potential range following the action potential upstroke can offset depolarizing I_{CaL} and hence lead to the less positive plateau phase in atrial compared with ventricular cardiomyocytes. Conversely, block of I_{Kur} produces a more pronounced spike-and-dome configuration and therefore shifts the potential into a more positive range in which I_{CaL} activation enhances systolic Ca^{2+} influx during a free-running action potential. Such an indirect effect on I_{CaL} should be shared by all I_{Kur} blockers and is expected to result in a positive atrial inotropic effect.¹⁸

Inherited Channelopathies

KCNA5 mutations have been reported in individuals with familial AF. Heterologous expression of these mutations revealed complete I_{Kur} loss of function (see Table 2.3). Absence of I_{Kur} can excessively prolong atrial action potential duration with an enhanced risk of EADs that can trigger or maintain AF.

Acquired Diseases

A prolonged period of rapid activation of the atria as occurs during AF leads to a decrease in I_{Kur} . In addition, I_{Kur} may be affected in myocardial ischemia (see eFig. 2.1). Decreased $K_v1.5$ mRNA levels were reported for the epicardial border zone of infarcted hearts. Moreover, ischemic damage disrupted the normal location of $K_v1.5$ in the intercalated discs.

Rapidly Activating Delayed Outward Rectifying Current

Structure and Physiology

I_{Kr} is formed by coassembly of four pore-forming α subunits ($K_v11.1$, encoded by *KCNH2*) and β subunits (MiRP1, encoded by *KCNE2*). *KCNH2* is also known as the human-ether-a-go-go-related gene (*HERG*), so-named because the mutation in the *Drosophila* fruit fly caused it to shake like a go-go dancer. The current generated by *HERG* channels shows unusual voltage dependence. In contrast to I_{Ks} , I_{Kr} activates relatively rapidly (on the order of 10s of milliseconds) on membrane depolarization. Activation of I_{Kr} occurs with steep voltage dependence and reaches half-maximum activation at membrane voltage of approximately -20 mV. The magnitude of I_{Kr} increases as a function of E_m up to approximately 0 mV, but it declines with stronger depolarization (higher than 0 mV), resulting in a negative slope conductance of the current-voltage relationship. During repolarization of the action potential, I_{Kr} rapidly recovers from inactivation, thus causing the current to peak at -40 mV. The amplitude of the tail current on repolarization exceeds that of the current during the depolarizing pulse.²³

The unusual voltage dependence of I_{Kr} results from a fast, voltage-dependent C/P-type inactivation process, which limits outward K^+ flow at positive voltages. The large tail current on repolarization from positive voltages results from the rapid recovery of inactivated channels into a conducting state. On repolarization, *HERG* channels deactivate (close) via a slow, voltage-independent process (in contrast to the voltage-dependent inactivation process).

Unlike most K_v channels, *HERG* channels exhibit inward rectification. Rectification describes the property of an ion channel to allow currents preferentially to flow in one direction or limit currents from flowing in the other direction. In other words, conductivity of channels

carrying such currents is not constant but is altered at a different E_m . A channel that is inwardly rectifying is one that passes current (positive charge) more easily into the cell. This property is critical for limiting outward K^+ conductance during the plateau phase of the cardiac action potential. Unlike typical K_{ir} channels, in which rectification derives from blockade of the channel pore by intracellular polyamines (see later discussion), the mechanism of *HERG* inward rectification is a very rapid inactivation that develops at far more negative potentials (-85 mV) than channel activation (-20 mV).

The inactivation of *HERG* channels resembles the C/P-type inactivation of other K_v channels in its sensitivity to extracellular cations (including K^+ and Na^+) and tetraethyl ammonium (TEA), and to mutations in the P segment. However, the gating behavior is distinctive. First, channel inactivation is much faster than voltage-dependent activation, thus resulting in its characteristic rectification. Second, *HERG* inactivation displays intrinsic voltage dependence. Similar to the classic C/P-type inactivation, raising the concentration of extracellular K^+ slows *HERG* channel C/P-type inactivation, an effect that appears to result from occupancy of the pore selectivity filter by K^+ .

Function

I_{Kr} presents the principal repolarizing current at the end of the plateau phase in most cardiac cells and plays an important role in governing the cardiac action potential duration and refractoriness. I_{Kr} is differentially expressed, with high levels in left atrial and in ventricular endocardium.

I_{Kr} activates relatively fast on membrane depolarization and allows outward diffusion of K^+ ions in accordance with its electrochemical gradient, but voltage-dependent inactivation thereafter is very fast. Hence only limited numbers of channels remain in the open state, while a considerable fraction resides in the nonconducting inactivated state. The fast voltage-dependent inactivation limits outward current through the channel at positive voltages and thus helps maintain the plateau phase that controls contraction and prevents premature excitation. However, as the voltage becomes less positive at the end of the plateau phase of repolarization, the channels recover rapidly from inactivation, thus leading to a progressive increase in I_{Kr} amplitudes during action potential phases 2 and 3, with maximal outward current occurring before the final rapid declining phase of the action potential. The large resurgent I_{Kr} outward current repolarizes the membrane potential. Next, the channel deactivates (closes) slowly. The resulting large and transient outward current adds considerably to the ongoing repolarization and makes *HERG* especially suitable for robust control of the repolarization phase.^{23,25}

Regulation

β -Adrenergic stimulation and elevation of intracellular cAMP levels enhance I_{Kr} amplitude both through PKA-mediated effects and by direct interaction with the protein. α -Adrenergic stimulation is inhibitory. Coexpression of *HERG* with its β subunit (*KCNE1* or *KCNE2*) accentuates the cAMP-induced voltage shift. The net result of these effects is a reduction in I_{Kr} .

Extracellular Na^+ potentially inhibits I_{Kr} by binding to an outer pore site, and it also speeds recovery from inactivation. The inhibitory effect of Na^+ is potentially relieved by physiological levels of extracellular K^+ . Competition with external K^+ for a binding site near the external pore explains the finding that elevation of extracellular K^+ concentration paradoxically enhances I_{Kr} despite the decrease in the electrochemical driving force. Hypokalemia causes prolongation of the action potential duration as a result of reduced K^+ conductance. Low extracellular K^+ levels accelerate fast inactivation of the *HERG* channel and increase channel blockade by extracellular Na^+ .²⁶

Pharmacology

I_{Kr} is the target of class III antiarrhythmic drugs of the methanesulfonanilide group (almokalant, dofetilide, D-sotalol, E-4031, ibutilide, and MK-499). These drugs produce a voltage- and use-dependent block, shorten open times in a manner consistent with open channel block, and exhibit low affinity for closed and inactivated states. I_{Kr} blockers prolong atrial and ventricular action potential duration (and the QT interval) and refractoriness in the absence of significant changes in conduction velocity (AH, HV, and PR intervals do not prolong). Although selective I_{Kr} blockers exhibit antiarrhythmic properties against reentrant arrhythmias, they are probably not effective against triggered activity or increased automaticity.

Selective I_{Kr} blockers have several disadvantages. These drugs tend to prolong the action potential duration in the Purkinje and midmyocardial cells more than in the subepicardial or subendocardial cells, thus resulting in increased dispersion of repolarization across the ventricular wall and, as a consequence, increased arrhythmogenesis. Moreover, the effects of these drugs increase with decreasing heart rate. This reverse frequency-dependent nature of I_{Kr} blockers can potentially result in excessive prolongation of the QT interval during bradycardia, potentially precipitating torsades de pointes, whereas this prolongation is much less marked or even absent following β -adrenergic stimulation or during sustained tachycardia. This phenomenon limits the efficacy of these drugs in terminating tachyarrhythmias, while maximizing the risk of torsades de pointes during slow heart rates, such as during sinus rhythm after termination of AF. Reverse use-dependence has been attributed, at least in part, to the incomplete deactivation (accumulation) of I_{Kr} during fast heart rates that leads to a progressive increase in current amplitude, which counteracts the action potential prolongation effects of I_{Kr} blockers.

Azimilide blocks I_{Kr} , I_{Ks} , and I_{CaL} , whereas amiodarone exhibits a complex mechanism of action because it blocks I_{Na} , I_{Ca} , I_{Kr} , I_{Ks} , I_{to} , and I_{KATP} . Quinidine, a class IA agent, also blocks I_{Kr} at concentrations lower than those required to block I_{Ks} , I_{to} , and I_{K1} .

Furthermore, *HERG* channels display an unusual susceptibility to blockade by a variety of drugs compared with other voltage-gated K^+ channels. Increasing numbers of drugs with diverse chemical structures (including some antihistaminics, antipsychotics, and antibiotics) decrease I_{Kr} by depressing *HERG* channel gating, delay ventricular repolarization, prolong the QT interval (acquired LQTS), and induce torsades de pointes. In fact, almost all drugs that cause acquired LQTS target *HERG* channels, likely because of unique structural properties rendering this channel unusually susceptible to a wide range of different drugs. Compared with other cardiac K^+ channels, the *HERG* channel has a large, funnel-like vestibule that allows many small molecules to enter and block the channel. The more spacious inner cavity results from a lack of the S6 helix bending Pro-X-Pro sequence, which presumably facilitates access of drugs to the pore region from the intracellular side of the channel to block the channel current. In addition, the *HERG* channel contains two aromatic residues located in the S6 domain facing the channel vestibule (not present in most other K^+ channels) that provide high-affinity binding sites for a wide range of structurally diverse compounds. The accessory β subunit (*MiRP1*, *KCNE2*) also determines the drug sensitivity. Interaction of these compounds with the channel's pore causes functional alteration of its biophysical properties or occlusion of the permeation pathway.^{18,23}

One novel mechanism for acquired LQTS involves compounds interfering with *HERG* trafficking (i.e., moving the *HERG* protein from the endoplasmic reticulum to the cell membrane), rather than direct pore blocking. These compounds include arsenic trioxide, pentamidine, probucol (a cholesterol-lowering therapeutic compound), and cardiac glycosides.²³

Some drugs (almokalant, norpropoxyphene, azimilide, candesartan, and E3174, the active metabolite of losartan) can enhance I_{Kr} . Flufenamic acid and niflumic acid also increase I_{Kr} by accelerating channel opening. These observations open the possibility of developing new I_{Kr} openers for the treatment of patients with congenital (LQT2) or drug-induced LQTS.

Inherited Channelopathies

Long QT syndrome. The LQTS variants in which I_{Kr} is dysfunctional include LQT2 (caused by *KCNH2* [*HERG*] loss-of-function mutations) and LQT6 (caused by *KCNE2* [*MiRP1*] mutations; see Table 2.3). LQT2 is the second most prevalent type of LQTS. More than 200 putative disease-causing mutations have been identified for *KCNH2*; most appear to disrupt the maturation and trafficking of I_{Kr} α subunit ($K_{v11.1}$) to the sarcolemma, thereby reducing the number of functional ion channels at the cell surface membrane. Mutations involving the pore region of the *HERG* channel are associated with a significantly more severe clinical course than nonpore mutations; most pore mutations are missense mutations with a dominant negative effect. Attenuation of I_{Kr} results in prolongation of the action potential and the QT interval and can potentially generate EADs and torsades de pointes.²³

The trafficking of some mutant channels into the sarcolemma can be restored by *HERG* channel blockers (e.g., cisapride, terfenadine, astemizole, E-4031), even when fexofenadine rescues mutant *HERG* channels at concentrations that do not cause channel block. However, because I_{Kr} blockers failed to rescue other trafficking-defective mutants, it is likely that multiple mechanisms underlie the pharmacological rescue of LQT2 mutations.

Proarrhythmia induced by conditions associated with reduction of I_{Kr} (acquired and congenital LQTS) is related to excessive prolongation of action potential duration near plateau voltages, especially those that favor the development of EADs. It is also related to a more marked prolongation of the action potential duration in midmyocardial than in subepicardial or subendocardial ventricular cells, possibly because of the relative scarcity of I_{Ks} and hence less “repolarization reserve” in the midmyocardial cells. Thus triggered focal activity and ventricular reentry associated with an increased heterogeneity of repolarization across the ventricular wall would lead to the development of torsades de pointes.²⁷

Short QT syndrome. Short QT syndrome (SQTS) is a rare disease associated with short QT intervals and increased risk for AF and VF. A gain-of-function mutation in *KCNH2* (*HERG*) is linked to SQTS type 1 (SQT1). The *KCNH2* mutation causes a shift of voltage dependence of inactivation of I_{Kr} to more depolarized potentials (by +90 mV) out of the range of the action potential, leading to less inward rectification at physiological potentials and a significant increase of I_{Kr} during the action potential plateau at the expense of the magnitude of the repolarizing tail current. The resulting I_{Kr} increase achieved by altered gating hastens repolarization, thereby shortening action potential duration and facilitating reentrant excitation waves to induce atrial and ventricular arrhythmia.^{23,27}

Familial AF. Gain-of-function mutations in *KCNE2* (*MiRP1*) have been found in two families with AF. MI can result in reduction in $K_{v11.1}$ mRNA levels and I_{Kr} with consequent prolongation of the action potential duration (see eFig. 2.1). Conversely, I_{Kr} density increases in subendocardial Purkinje cells in the infarcted heart at 48 hours, which can potentially increase the proarrhythmic effects of I_{Kr} blockers in patients with MI. In addition, during acute ischemia, I_{Kr} is increased and action potential duration is shortened. Such changes can be arrhythmogenic. I_{Kr} is unchanged in patients with chronic AF and is homogeneously distributed in failing canine hearts.

ATP, derived from either glycolysis or oxidative phosphorylation, is critical for *HERG* channel function. Both hyperglycemia and hypoglycemia depress I_{Kr} and can cause QT prolongation and ventricular arrhythmias. In diabetes, $K_{v11.1}$ levels are downregulated, leading to reduction in I_{Kr} and contributing to QT interval prolongation. Importantly, insulin therapy restores I_{Kr} function and shortens QT intervals.

Unlike with most other K^+ currents, I_{Kr} amplitude increases on elevation of extracellular K^+ concentrations and decreases after removal of extracellular K^+ . Elevation of extracellular K^+ concentration reduces C/P-type inactivation and increases the single channel conductance of *HERG* channels. This explains why the action potential durations are shorter at higher extracellular K^+ concentrations and longer at low concentrations, and it clarifies the associations among hypokalemia, action potential duration prolongation, and induction of torsades de pointes in patients treated with I_{Kr} blockers. In contrast, modest elevations of extracellular K^+ concentrations using K^+ supplements and spironolactone in patients given I_{Kr} blockers or with LQT2 significantly shorten the QT interval and may prevent torsades de pointes. Moreover, the antiarrhythmic actions of I_{Kr} blockers can be reversed during ischemia, which is frequently accompanied by elevations of the extracellular K^+ concentrations in the narrow intercellular spaces and by catecholamine surges that occur with exercise or other activities associated with fast heart rates.

Slowly Activating Delayed Outward Rectifying Current Structure and Physiology

I_{Ks} is formed by coassembly of four pore-forming α subunits ($K_{v7.1}$, also known as K_{vLQT1} , encoded by the *KCNQ1* gene) and β subunits (minK, encoded by the *KCNE1* gene). I_{Ks} is a K^+ -selective current that activates very slowly in response to membrane depolarization to potentials greater than −30 mV and reaches half-maximum activation close to +20 mV. I_{Ks} has a linear current-voltage relationship, its time course of activation is extremely slow, slower than any other known K^+ current, and steady-state amplitude is achieved only with extremely long membrane depolarization.²³

Inactivation of *KCNQ1* channels is half-maximal at −18 mV. At its maximum, inactivation reduces fully activated current by approximately 35%. In addition, unlike inactivation of other K_v channels, the onset of I_{Ks} inactivation occurs after a delay (a delay of approximately 75 milliseconds at +40 mV). In contrast, when inactivation is induced after transient recovery of channels to open states, the onset of inactivation is 10 times faster. The molecular mechanism of *KCNQ1* channel inactivation is unknown, but in contrast to a classical C/P-type inactivation, *KCNQ1* inactivation is independent of extracellular K^+ concentration.

Function

I_{Ks} contributes to human atrial and ventricular repolarization, particularly during action potentials of long duration. I_{Ks} gradually increases during the plateau phase of the action potential because its activation is delayed and very slow. As a consequence, the contribution of I_{Ks} to the net repolarizing current is greatest late in the cardiac action potential plateau phase. I_{Ks} is expressed in all cell types, but it is reduced in midmyocardial cells. The midmyocardial cells have the longest action potential duration across the myocardial wall.

I_{Ks} plays an important role in determining the rate-dependent shortening of the cardiac action potential and QT interval. As heart rate increases, I_{Ks} increases because channel deactivation is slow and incomplete during the shortened diastole. This allows I_{Ks} channels to accumulate in the open state during rapid heart rates and contribute to the faster rate of repolarization.

Importantly, I_{Ks} is functionally upregulated when other repolarizing currents (e.g., I_{Kr}) are reduced, potentially serving as a safeguard against

loss of repolarizing power. As such, several redundant mechanisms contribute to repolarization constituting the repolarization reserve, in which I_{Ks} plays an important role.

Regulation

I_{Ks} is markedly enhanced by β -adrenergic stimulation through channel phosphorylation by PKA (requiring A-kinase anchoring protein 9 [AKAP9, also known as Yotiao]) and PKC (requiring minK). This produces a rate-dependent shortening of the action potential duration, such as seen during exercise-induced sinus tachycardia. I_{Ks} is also modulated by α -adrenergic receptors through the PKC pathway. Lowering extracellular K^+ and Ca^{2+} concentrations increases I_{Ks} .²⁸

Coexpression of $K_{v7.1}$ with minK regulates α subunit trafficking and behavior and results in a sevenfold increase in I_{Ks} magnitude, marked slowing of the time course of activation, and removal (or significant slowing) of inactivation of $K_{v7.1}$ channels.

As noted, I_{Kr} and I_{Ks} are functionally linked; when I_{Kr} is reduced, the action potential is prolonged, causing I_{Ks} activation to increase to prevent excess repolarization delay. Hence the duration of the action potential is very tightly tuned via I_{Ks} and I_{Kr} regulation.

Pharmacology

I_{Ks} is resistant to methanesulfonanilides (almokalant, dofetilide, D-sotalol, E-4031, ibutilide, and MK-499), but it is selectively blocked by chromanols, indapamide, thiopentone, propofol, and benzodiazepines. I_{Ks} is also blocked, although nonselectively, by amiodarone, dronedarone, and azimilide. β subunits (minK) modulate the effects of I_{Ks} blockers and agonists. In fact, coexpression of $K_{v7.1}$ with minK confers 6- to 100-fold higher affinity for some I_{Ks} blockers than $K_{v7.1}$ channels.

Selective I_{Ks} blockers prolong the cardiac action potential duration and QT interval and suppress electrically induced ventricular tachyarrhythmias in animals with acute coronary ischemia and exercise superimposed on a healed MI.

I_{Ks} blockade seems to have less proarrhythmic potency as compared with I_{Kr} blockade, likely the result of less drug-induced dispersion in repolarization. In addition, because I_{Ks} accumulates at fast driving rates because of its slow deactivation, I_{Ks} blockers can be expected to be more effective in prolonging action potential duration and refractoriness tachyarrhythmias, with lesser effects at normal sinus rates. Furthermore, since I_{Ks} activation occurs at approximately 0 mV and this voltage is more positive than the Purkinje fiber action potential plateau voltage, I_{Ks} blockade should not be expected to prolong the action potential duration at this level. Conversely, in ventricular muscle, the plateau voltage is more positive (approximately +20 mV), thus allowing I_{Ks} to be substantially more activated, so that I_{Ks} blockade would be expected to markedly increase action potential duration.²⁰

β -Adrenergic agonists increase I_{Ks} density and produce a rate-dependent shortening of the action potential duration, and can also decrease the antiarrhythmic effects of I_{Ks} blockers. In addition, in the presence of I_{Ks} blockade, isoproterenol seems to abbreviate the action potential duration of epicardial and endocardial, but not midmyocardial, cells, an effect that can accentuate transmural dispersion of repolarization and precipitate torsades de pointes. These observations may explain the therapeutic actions of beta-blockers in patients with LQTS syndromes linked to attenuation of I_{Ks} and the increased risk of fatal cardiac arrhythmias under physical activity or stressful situations that increase sympathetic activity in these patients.

Inherited Channelopathies

KCNQ1 and *KCNE1* mutations can lead to a defective protein and several forms of inherited arrhythmias, including LQTS (comprising

the autosomal dominant Romano-Ward syndrome and the autosomal recessive Jervell and Lange-Nielsen syndrome), SQTs, and familial AF.

Long QT syndrome. The most common type of LQTS, LQT1, is caused by loss-of-function mutations on the *KCNQ1* gene (*K_vLQT1*). To date, more than 200 mutations of this gene have been reported. They comprise many Romano-Ward (autosomal dominant) syndromes and account for approximately 45% of all genotyped LQTS families. Individuals with the less prevalent LQTS type 5 (LQT5) carry loss-of-function autosomal dominant mutations in *KCNE1* and display a phenotype similar to that seen in patients with LQT1.²³

Loss-of-function mutations in both alleles of *KCNQ1* or *KCNE1* (i.e., inherited from both parents, autosomal recessive) cause the very rare Jervell and Lange-Nielsen syndrome type 1 or 2, respectively. Jervell and Lange-Nielsen syndrome is characterized by severe QT interval prolongation, high risk of sudden death, and congenital deafness; the deafness results from deficient endolymph secretion (*KCNQ1* and *KCNE1* are also expressed in the inner ear, where they enable endolymph secretion).²⁷

LQT11 is caused by loss-of-function mutations on the *AKAP9* gene, which encodes an A-kinase anchoring protein (Yotiao), shown to be an integral part of the I_{Ks} macromolecular complex. The presence of Yotiao is necessary for the physiological response of the I_{Ks} channel to β -adrenergic stimulation. A mutation in *AKAP9* (Yotiao) in the I_{Ks} channel ($K_{v7.1}$) binding domain reduces the interaction between the I_{Ks} channel and Yotiao. This, in turn, reduces the cAMP-induced phosphorylation of the channel and prevents the functional response of the I_{Ks} channel to cAMP and adrenergic stimulation (i.e., prevents the increase in magnitude of I_{Ks} and the shortening of action potential duration in response to sympathetic stimulation). The final result is an attenuation of I_{Ks} , resulting in a delay in ventricular repolarization and QT interval prolongation.²³

Mutations in LQT1, LQT5, and LQT11 result in attenuation of I_{Ks} , which causes prolongation of repolarization, action potential duration, and QT interval, which may be especially notable during periods of increased sympathetic activity, such as exercise, when I_{Ks} becomes the predominant repolarization current rather than I_{Kr} . In LQT1, ventricular arrhythmias are usually triggered by emotional or physical stress, probably because mutant I_{Ks} does not increase sufficiently (i.e., has less repolarization reserve) during β -adrenergic stimulation. Accordingly, β -adrenergic blocking drugs suppress arrhythmic events in LQT1.

Short QT syndrome. SQT2 is caused by mutations on the *KCNQ1* gene (*K_vLQT1*). A gain-of-function *KCNQ1* mutation causes a shift of voltage dependence of activation of I_{Ks} by -20 mV and acceleration of activation kinetics, leading to enhancement of I_{Ks} and shortening of the action potential duration and QT interval. *KCNQ1* gain-of-function mutations likely predispose to AF and VF by shortening refractoriness and facilitating reentry.²³

Familial AF. *KCNQ1* gain-of-function mutations have been linked to familial AF, with or without the SQTs phenotype. In addition, gain-of-function mutations in the *KCNE1*, *KCNE2*, and *KCNE5*, which encode β subunits of I_{Ks} , have been linked to familial AF. Of note, a few loss-of-function mutations have been identified in patients with familial AF. The explanation of how gain- and loss-of-function mutations in the same channel could result in the same type of arrhythmia remains unclear.²⁷

Acquired Diseases

Heart failure reduces I_{Ks} in atrial, ventricular, and sinus node myocytes. Given that I_{Kr} is unchanged, I_{Ks} reduction may largely account for the prolonged action potential duration in heart failure (see eFig. 2.1).

I_{Ks} density and *KCNQ1/KCNE1* mRNA levels are reduced in myocytes from infarcted border zones 2 days after MI. However, *KCNQ1*

expression is restored 5 days after MI, whereas *KCNE1* expression remains decreased.

Inward Rectifying Current

Structure and Physiology

Kir family is categorized into seven subfamilies (Kir1-Kir7). Kir2 subfamily is responsible for the human I_{K1} . The Kir2 subfamily consists of six members (Kir2.1-Kir2.6), of which only three are expressed in human cardiac myocytes (Kir2.1, Kir2.2, and Kir2.3, encoded by *KCNJ2*, *KCNJ12*, and *KCNJ4*, respectively).²⁹

The Kir channels are formed by the coassembly of four α subunits (see Fig. 2.4). Each α subunit (Kir2.x) of I_{K1} consists of two transmembrane domains (M1 and M2) connected by a pore-forming P loop (H5) along with cytoplasmic N- and C-termini. The tetrameric Kir2 channel complex can be formed by identical (homotetramers) or different (heterotetramers) α subunits.²⁹

Kir channels exhibit a strong inward rectification property because conductance to K^+ ions alters at a different E_m . As noted, rectification describes the property of an ion channel to allow currents preferentially to flow in one direction or limit currents from flowing in the other direction. A channel that is inwardly rectifying is one that passes current (positive charge) more easily into the cell. In the case of Kir channels, inward rectification is a strongly voltage-dependent decline of K^+ efflux (i.e., reduction of outward current) on membrane depolarization that produces a characteristic region of so-called “negative slope conductance” (Fig. 2.5). At E_m more negative to the reversal potential for K^+ ($E_K = -90$ mV), I_{K1} conductance is much larger than that of any other current, and so it clamps the resting E_m close to E_K . On depolarization, I_{K1} channels close almost immediately and thus limit K^+ efflux at membrane potentials more positive than the E_K , remain closed throughout the plateau of the action potential, and open again at potentials negative to -20 mV. As such, I_{K1} channels also conduct a substantial outward current at an E_m between -40 and -90 mV. Within this voltage range, outward I_{K1} is larger at more negative potentials. Thus I_{K1} also contributes to terminal phase 3 of repolarization. Because an E_m negative to E_K is not reached in cardiomyocytes, only the outward I_{K1} plays a role in action potential formation.

The phenomenon of inward rectification of I_{K1} channels results from high-affinity and strongly voltage-dependent blockade of the inner

channel pore (at a site provided by a ring of negative charges) by cytosolic Mg^{2+} , Ca^{2+} , and positively charged polyamines (spermine, spermidine, putrescine), which plug the channel pore at depolarized potentials, resulting in a decline in outward currents, but are displaced by incoming K^+ ions at hyperpolarized potentials. This voltage-dependent block by polyamines causes currents to be conducted well only in the inward direction. As such, I_{K1} channels are voltage regulated despite the lack of the classic voltage-sensing mechanism of K_v channels.²⁰

Reducing overall membrane conductance and limiting K^+ efflux during the action potentials by inward rectification is an important energy-saving mechanism, since restoration of resting membrane state requires influx of the extruded K^+ ions by the Na^+-K^+ pump at the expense of ATP hydrolysis.²⁹

A unique property of I_{K1} is the unusual dependence of rectification on extracellular K^+ concentration. Specifically, on increase in extracellular K^+ , the I_{K1} current-voltage relationship shifts nearly in parallel with the E_K and leads to a crossover phenomenon (Fig. 2.6). One important consequence of such behavior is that at potentials positive to the crossover, K^+ conductance increases rather than decreases. This is against an expectation of a depolarization of the cell membrane based on a reduced driving force for K^+ ions (due to a less negative E_K) as a result of elevated extracellular K^+ concentration.¹⁷

Function

I_{K1} sets and stabilizes the resting E_m and regulates cellular excitability of atrial and ventricular myocytes during phase 4. It also contributes to the terminal portion of phase 3 repolarization. In addition to the contribution of I_{K1} to the T wave on surface ECG, data suggest that the U wave is strongly modulated by I_{K1} .

I_{K1} channels close on depolarization. The strong inward rectification of the I_{K1} limits the outward current during the positive phase of the action potential (phases 0, 1, and 2), thus allowing membrane depolarization following Na^+ channel activation, slowing membrane repolarization, and helping maintain a more prolonged cardiac action potential. This also confers energetic efficiency in the generation of the action potential.

I_{K1} density is much higher in ventricular than in atrial myocytes, a finding that explains the steep repolarization phase in the ventricles (where more abundant I_{K1} plays a larger role in accelerating the terminal portion of repolarization) and the shallower phase in the atria. The higher I_{K1} channel expression in the ventricle protects the ventricular cell from pacemaker activity. By contrast, I_{K1} is almost absent in sinus

Fig. 2.5 Idealized Current-Voltage Relation of Strong and Weak Kir Channels. Both conduct inward currents significantly at diastolic membrane potentials more negative to the reversal potential for K^+ ($E_K = -90$ mV). However, but strong inward rectifiers pass little or no current at action potential plateau potentials.

Fig. 2.6 Current-Voltage Relationship for Kir Channels at Two Different Extracellular K^+ Concentrations. E_K is calculated from the Nernst equation using extracellular $[K^+]$ of 5 or 12 mM and intracellular $[K^+]$ of 130 mM. (From Sorensen CM, Braunstein TH, Holstein-Rathlou N-H, Salomonsson M. Role of vascular potassium channels in the regulation of renal hemodynamics. *AJP Ren Physiol*. 2012;302:F505–F518.)

node and AVN cells, thus allowing for relatively more depolarized resting diastolic potentials compared with atrial and ventricular myocytes. In addition, location-dependent expression of specific Kir2 isoforms (Kir2.1, Kir2.2, Kir2.3) has been observed.

Fast heart rates increase K^+ concentration in the narrow intercellular space to several millimolars (secondary to K^+ efflux via I_{Kr} and I_{Ks} during repetitive action potentials) and augments I_{K1} , which results in a shortening of the action potential duration that may offset the ability of I_{Kr} blockers to prolong the action potential duration under these conditions.

Regulation

β -Adrenergic stimulation inhibits I_{K1} in ventricular myocytes via PKA-mediated phosphorylation of the channel. In atrial myocytes, α 1-adrenergic stimulation reduces I_{K1} via PKC-dependent pathways.

Kir2 overexpression increases I_{K1} density, shortens the action potential duration, and hyperpolarizes the resting E_m . In contrast, suppression of I_{K1} prolongs the action potential duration and disrupts effective clamping of the resting E_m , thus precipitating spontaneous pacemaker activity in otherwise nonpacemaking atrial and ventricular cardiomyocytes.

The phospholipid phosphatidylinositol 4,5-bisphosphate (PIP2) enhances I_{K1} and modulates various properties of Kir2 channels, such as pH sensitivity. In addition, increased levels of cholesterol in the membrane reduce I_{K1} . Various intracellular cations can block Kir2 channels, such as Ca^{2+} and H^+ (i.e., intracellular pH).

Pharmacology

Barium (Ba^{2+}) is a potent I_{K1} blocker. Blocking of I_{K1} by extracellular Ba^{2+} results in depolarization of the resting potential and mild action potential prolongation. Terikalant and chloroquine (an antimalarial drug) are strong I_{K1} inhibitors but can also block other K^+ channels.

Selective blockers of Kir2 channels are available only for experimental purposes. I_{K1} blockers prolong atrial and ventricular action potential duration and are effective against various types of experimental reentrant VTs. Moreover, I_{K1} blockers produce membrane depolarization, an effect that slows conduction velocity as a result of voltage-dependent inactivation of Na^+ channels, and prolongs the QT interval; both actions are proarrhythmic.²⁰

I_{K1} agonists include flecainide, arachidonic acid, tenidap (an anti-inflammatory agent), and zacopride (a gastrointestinal prokinetic agent).

Inherited Channelopathies

Long QT syndrome. Loss-of-function mutations of *KCNJ2* (encoding Kir2.1) result in dominant negative effects on the current and have been linked to Andersen-Tawil syndrome (LQT7), a rare autosomal dominant disorder characterized by the triad of skeletal developmental abnormalities, periodic paralysis, and usually ventricular arrhythmias (Kir2.1 channels are expressed primarily in skeletal muscle, heart, and brain). Compared with other types of LQTS, LQT7 is associated with more prominent U waves, a milder degree of QT interval prolongation, as well as a lesser risk of malignant ventricular arrhythmias.

Disruption of the I_{K1} function can potentially lead to prolongation of the terminal repolarization phase and QT interval, which can predispose to the generation of EADs and delayed afterdepolarizations (DADs) that cause ventricular arrhythmias. However, unlike other types of LQTS in which the afterdepolarizations arise from reactivation of L-type Ca^{2+} channels, the EADs and DADs generated in LQT7 are likely secondary to Na^+ - Ca^{2+} exchanger-driven depolarization. It is believed that the differential origin of the triggering beat is responsible for the observed discrepancy in arrhythmogenesis and the clinical features compared with other types of LQTS. In addition, it is likely that pro-

longation of the action potential duration in LQT7 is somewhat homogeneous across the ventricular wall (i.e., transmural dispersion of repolarization is less prominent than in other types of LQTS), and this can potentially explain the low frequency of torsades de pointes.

Catecholaminergic polymorphic ventricular tachycardia. Loss-of-function mutations of *KCNJ2* have been found in patients with catecholaminergic polymorphic ventricular tachycardia (CPVT) and may represent a CPVT phenocopy. These patients had prominent U waves, ventricular ectopy, and polymorphic VT, but no dysmorphic features or skeletal muscle abnormalities.

I_{K1} reduction can trigger arrhythmia by allowing inward currents, which are no longer counterbalanced by the strong outward I_{K1} , to depolarize the E_m gradually during phase 4. Membrane depolarization during phase 4 induces arrhythmia by facilitating spontaneous excitability.

Short QT syndrome. A gain-of-function mutation of *KCNJ2* has been identified and linked to SQTs type 3 (SQT3) (see Table 2.3). The mutation causes a significant increase in the outward I_{K1} at potentials between -75 mV and -45 mV, thus leading to acceleration of the terminal phase of repolarization and, as a consequence, shortening the action potential duration and QT interval and asymmetrical T waves with a rapid terminal phase.

Familial AF. A gain-of-function *KCNJ2* mutation has been linked to familial AF. The affected members had normal QT intervals. The mutation was speculated to cause AF by shortening atrial action potential duration and facilitating reentrant excitation waves.

Acquired Diseases

I_{K1} is downregulated in patients with severe heart failure and cardiomyopathy (see eFig. 2.1). The downregulation of I_{K1} produces membrane depolarization and prolongation of the action potential duration, and it can facilitate spontaneous excitability and trigger arrhythmia (both EADs and DADs). Ventricular myocytes from patients with idiopathic dilated cardiomyopathy exhibit decreased channel activity, longer action potential duration, and a lower resting E_m than those from patients with ischemic cardiomyopathy. Upregulation of I_{K1} can be observed in ventricular hypertrophy.

Atrial I_{K1} is upregulated in patients with chronic AF, resulting in more negative resting potentials and, together with reduced I_{CaL} , accounting for action potential shortening in AF.

Acetylcholine-Activated Potassium Current

Structure and Physiology

I_{KACH} results from a heterotetrameric complex of two Kir3.1 (GIRK1, encoded by *KCNJ3*) and two Kir3.4 (GIRK4, encoded by *KCNJ5*) α subunits. I_{KACH} is a receptor-activated Kir channel; it has large cytoplasmic domains that harbor specific binding sites for cytosolic effectors (G proteins). The channel conducts I_{KACH} in response to the stimulation of G protein-coupled muscarinic (M2) and adenosine (A1) receptors. Because channel gating requires a G protein, Kir3.1/ Kir3.4 are considered a type of KG channel (hence the terminology GIRK1/GIRK4).

Cardiac I_{K1} and I_{KACH} are the major K^+ currents displaying classical strong inward rectification with membrane depolarization, a unique property that is critical for their roles in cardiac excitability.

Function

I_{KACH} has generally an opposite distribution to that of I_{K1} . I_{KACH} is more prominent in atrial tissue, as well as in the sinus node and AVN, and is largely absent in the ventricles. The regional distribution of I_{KACH} is also heterogeneous within and between the atria.¹⁷

I_{KACH} mediates vagal influences on sinus rate and atrial repolarization, as well as AVN conduction. Activation I_{KACH} by acetylcholine

hyperpolarizes the E_m and shortens action potential duration. These effects result in slowing of phase 4 depolarization, reduction in the spontaneous firing rate of the pacemaker cells of the sinus node, and slowing of AVN conduction. These effects explain why vagal maneuvers or IV adenosine can terminate reentrant supraventricular tachycardias using the AVN.

Regulation

Vagal stimulation produces a nonuniform shortening of the atrial action potential duration and refractoriness mediated by activation of $I_{K_{ACH}}$, an effect that can contribute to the perpetuation of AF.²⁸

$I_{K_{ACH}}$ is also increased by purinergic stimulation. Adrenergic stimulation via β_1 -receptor-mediated signaling increases the amplitude of constitutively active current, whereas α_1 -stimulation decreases $I_{K_{ACH}}$.

Atrial $I_{K_{ACH}}$ is inhibited by membrane stretch, possibly serving as a mechanoelectrical feedback pathway, a property conferred by the Kir3.4 subunit.

Pharmacology

$I_{K_{ACH}}$ activity can be stimulated by intracellular ATP, PIP2, ETA endothelin, A opioid, and α_2 -adrenergic agonists. α_1 -Adenosine receptor agonists stimulate $I_{K_{ACH}}$, whereas methylxanthines, such as theophylline and aminophylline, antagonize the effects of adenosine. Dipyridamole prolongs the action of adenosine by disturbing the action of the cell membrane transporter of adenosine.

$I_{K_{ACH}}$ is inhibited by several antiarrhythmic drugs, including amiodarone, dronedarone, dofetilide, ibutilide, sotalol, terikalant, disopyramide, procainamide, flecainide, and propafenone. Disopyramide and procainamide mainly block the muscarinic receptors, whereas flecainide and propafenone act as open channel blockers. Blockade of $I_{K_{ACH}}$ by dronedarone is approximately 100 times more potent than that of amiodarone.²⁰

$I_{K_{ACH}}$ is regarded as an atrial-selective drug target. A potent $I_{K_{ACH}}$ blocking property can be of a particular therapeutic value for treatment of AF, because $I_{K_{ACH}}$ plays a prominent role in vagally induced AF and has been shown to be constitutively active in chronic AF. In fact, several newer compounds targeting $I_{K_{ACH}}$ are currently being evaluated in pre-clinical and clinical studies for AF therapy. Inhibition of $I_{K_{ACH}}$ in the setting of AF can potentially produce proportionally greater action potential duration prolongation than under control conditions and can even terminate experimental atrial tachyarrhythmias and AF without ventricular side effects.²⁴

Inherited Channelopathies

LQT13 is caused by loss-of-function mutations on the *KCNJ5* gene. The *KCNJ5* mutation exerts dominant-negative effects on Kir3.1/Kir3.4 channel complexes by disrupting membrane targeting and stability of Kir3.4.

Acquired Diseases

Evidence indicates that constitutively active $I_{K_{ACH}}$ channels develop during AF as part of the electrical remodeling processes (i.e., these channels become activated despite the absence of stimulating acetylcholine). This increase in functionally uncoupled $I_{K_{ACH}}$ in human AF is possibly the result of increased phosphorylation of Kir3 channels by PKC or a reduction in inhibitory G α_i -3 subunits (see eFig. 2.1). Constitutively active $I_{K_{ACH}}$ can hyperpolarize the membrane and hence contribute to AF-related electrical remodeling and to the persistence of AF by stabilization of rotors. Therefore selectively targeting constitutively active $I_{K_{ACH}}$ channels only may preserve physiological stimulation by vagal nerves and could serve as a promising remodeling-related drug target.²⁰

Adenosine Triphosphate–Sensitive Potassium Current Structure and Physiology

Cardiac ATP-sensitive K^+ (K_{ATP}) channels (also termed the adenosine diphosphate [ADP]–activated K^+ channel) are formed by the unique combination of two dissimilar proteins: four pore-forming α subunits (Kir6) and four regulatory ABC proteins (SUR subunits). Two Kir6 genes, *KCNJ8* (encoding Kir6.1) and *KCNJ11* (encoding Kir6.2), and 2 SUR genes, *ABCC8* (encoding SUR1) and *ABCC9* (encoding SUR2), encode mammalian K_{ATP} subunits (Fig. 2.7). Alternative splicing of mRNA products give rise to multiple SUR variants (e.g., SUR2A and SUR2B), which confer distinct functional and pharmacologic properties on K_{ATP} channels.¹⁶

K_{ATP} channels are found in virtually every kind of cardiac tissue and, to a lesser extent, vascular smooth muscle. Current evidence suggests that K_{ATP} channels in ventricular myocytes are composed primarily of Kir6.2 and SUR2A isoforms, whereas K_{ATP} channels in atrial myocytes are composed primarily of Kir6.2 and SUR1 subunits. Kir6.1 subunits may contribute to the formation of K_{ATP} channels in SAN, AVN, and Purkinje fiber cells.¹⁶

The Kir6 subunits have two transmembrane domains (M1, M2) bridged by an extracellular loop that generates the narrow portion of the pore and controls ion selectivity, and large cytoplasmic domains that provide the binding sites for ATP.

The ATP-binding cassette transporter family consists of seven subfamilies (ABCA to ABCG) with 48 subfamily members. Most of the ABC proteins transport various molecules across cell membranes at the expense of ATP hydrolysis. The SUR subunits are much larger than Kir6 subunits and have 17 transmembrane regions, arranged in three transmembrane domains (TMD0, TMD1, and TMD2). TMD1 and TMD2 each contain six transmembrane segments and nucleotide-binding domains on the cytoplasmic side (known as nucleotide-binding folds [NBFs] that contain the characteristic Walker A and B motifs). TMD0 contains five transmembrane segments and is critical for trafficking and gating of the channel complex. The SUR subunits allow for nucleotide-mediated regulation of K_{ATP} and are critical in its role as a sensor of metabolic status. The SUR2A subunits are also sensitive to sulfonylureas, Mg-ATP, Mg-ADP, and some other pharmacological channel openers. In addition, SUR2A subunit harbors an ATPase for ATP hydrolysis, which gates the K^+ permeation through the Kir6.2 α subunit. Kir6 subunits are unique among the K^+ channel subunits since the presence of an auxiliary SUR subunit is an absolute requirement to form a functional channel. The details of the physical connection between Kir6 and SUR subunits remain unclear.^{29,30}

K_{ATP} is a receptor-activated weak inward rectifier channel, regulated by intracellular ATP and ADP concentrations. An increase in the ratio of ATP to ADP closes the channel, and a decrease opens it, linking the metabolic state to the cellular E_m . Further, physiological levels of intracellular Na^+ and Mg^{2+} and naturally occurring intracellular polyamines (e.g., spermine, spermidine, and putrescine) contribute to K_{ATP} channel inward rectification.

Function

$I_{K_{ATP}}$ is inhibited by intracellular ATP and activated by Mg-ADP, so that the channel activity is regulated by the ATP/ADP ratio, coupling cell metabolism to the E_m . In responding to cytoplasmic nucleotide levels, K_{ATP} channel activity provides a unique link between cellular energetics and electrical excitability and hence contractility. Under normal metabolic conditions, sarcolemmal K_{ATP} channels are predominantly closed (inhibited by intracellular ATP), and they do not significantly contribute to the cardiac action potential, resting E_m , or cell excitability. However, when exposed to a severe metabolic stress such as anoxia, metabolic

Fig. 2.7 Membrane Topology and Structural Organization of the Subunits of the Adenosine Triphosphate-Sensitive Potassium Channel. The channel consists of four members of the Kir6 subfamily members (Kir6.1 and/or Kir6.2) and four members of the sulfonylurea receptor family (SUR1 and/or SUR2; or splice variants of these subunits). The Kir6.x subunit has two membrane-spanning regions (M1 and M2) with intracellular NH₂ and COOH termini. The SURx subunit has 17 transmembrane regions, arranged in three domains: TMD0, TMD1, and TMD2. An intracellular nucleotide binding fold (NBF1), with Walker A and Walker B domains, exists between TMD1 and TMD2. A second intracellular nucleotide binding fold (NBF2) exists in the COOH terminus region of the protein. It is thought that NBF1 binds (and hydrolyzes) Mg-ATP, whereas Mg-ADP binds primarily to NBF2 to stimulate channel activity. ATP blocks the channel by direct binding to Kir6.x intracellular domains, whereas Mg²⁺-complexes of nucleotides regulate the channel activity by binding to intracellular nucleotide binding folds (NBF1 and NBF2) of the SURx subunits. ADP, Adenosine diphosphate; ATP, adenosine triphosphate; Mg, magnesium. (From Foster MN, Coetzee WA. K_{ATP} channels in the cardiovascular system. *Physiol Rev.* 2016;96:177–252.)

inhibition, or ischemia, K_{ATP} channels become activated (secondary to reduced intracellular ATP levels) and conduct an outward repolarizing K⁺ current (I_{KATP}), which results in abbreviation of the action potential duration and reduction of Ca²⁺ influx through L-type Ca²⁺ channels. By reducing Ca²⁺ entry, I_{KATP} depresses muscle contractility, thereby conserving scarce energy resources, and prevents the damaging effects of intracellular Ca²⁺ overload.^{17,28}

Accordingly, cardiac K_{ATP} channels act as membrane-based metabolic sensors that receive energetic signals of cellular distress and provide adaptive response to acute stress capable of controlling cardiac action potential duration and associated cellular functions and adjusting cellular excitability to match demand.^{29,30}

In addition, activation of I_{KATP} plays an important role in ischemic preconditioning; brief periods of myocardial ischemia confer protection against subsequent prolonged ischemia, reducing MI size, severity of myocardial stunning, and the risk of cardiac arrhythmias. Experimental studies found that K_{ATP} channel openers reproduce the effects of preconditioning, while I_{KATP} blockers prevent the protective effects of ischemic preconditioning. However, the role of sarcolemmal I_{KATP} channels in ischemic preconditioning versus that of mitochondrial I_{KATP} channels

(which appear to be pharmacologically distinct from sarcolemmal I_{KATP}) has been debated.^{28,31}

On the other hand, activation of I_{KATP} also results in shortening of the action potential duration, accumulation of extracellular K⁺, membrane depolarization, and slowed conduction velocity—effects that render the ischemic heart vulnerable to reentrant arrhythmias.

K_{ATP} channels have been further implicated in the adaptive cardiac response to chronic pathophysiological hemodynamic load. K_{ATP} channel deficiency affects structural remodeling, renders the heart vulnerable to Ca²⁺-dependent maladaptation, and predisposes to heart failure.

In the vasculature, activation of K_{ATP} channels results in hyperpolarization of the membrane potential, leading to inhibition of voltage-sensitive Ca²⁺ channels and lowering of intracellular Ca²⁺, with consequent vasodilation.³⁰

Regulation

ATP (with or without Mg²⁺) inhibits I_{KATP} by interacting directly with Kir6.2 and stabilizing the closed state of the channel. In addition, in the presence of Mg²⁺, ATP and ADP can activate the channel through interaction with the SUR2A subunit. Inhibition by ATP binding to

Fig. 2.8 Regulation of ATP-sensitive potassium (K_{ATP}) Channels by Intracellular Nucleotides. The K_{ATP} channel is composed of four Kir6.x and four SURx subunits (respectively color coded in blue and orange). Channel activity is inhibited by intracellular adenosine triphosphatase (ATP). In the presence of magnesium (Mg)-ATP, adenosine diphosphate (ADP) stimulates K_{ATP} channel opening, such that the channel is regulated by the ADP-to-ATP ratio. Even a small decrease in ATP levels during metabolic stress translates to a relatively large increase in adenosine monophosphate (AMP) levels, which may indirectly further stimulate K_{ATP} channel opening and promote surface trafficking through the actions of the trimeric AMP-activated protein kinase (AMPK) and adenylate kinase. (From Foster MN, Coetzee WA. K_{ATP} channels in the cardiovascular system. *Physiol Rev.* 2016;96:177–252.)

Kir6.2 and activation by Mg-nucleotides is the primary physiological regulatory mechanism (Fig. 2.8).

K_{ATP} channel's sensitivity to ATP is not fixed, and it can be modulated by other cellular factors. Nucleotide diphosphates, lactate, oxygen-derived free radicals, and adenosine α_1 receptor stimulation desensitize K_{ATP} to inhibition by intracellular ATP. In addition, the phospholipid PIP2 directly interacts with Kir6.2 subunit stabilizing the open state of the channel and antagonizes ATP inhibition of I_{KATP} .

Pharmacology

K_{ATP} channels can be inhibited or activated by a variety of drugs, all acting on the SUR subunit. K_{ATP} channel openers (pinacidil, cromakalim, rimakalim, and nicorandil) bind at two distinct regions of SUR2A subunits and can exert cardioprotective effects in patients with acute MI. However, K_{ATP} channel openers also activate vascular K_{ATP} (Kir6.1/SUR2B) and produce hypotensive effects that limit their use in the treatment of myocardial ischemia. Moreover, because I_{KATP} density is larger in the epicardium, K_{ATP} channel openers produce a more marked shortening of action potential duration in epicardial cells, thus leading to a marked dispersion of repolarization and to the development of extrasystolic activity via a mechanism of phase 2 reentry. On the other hand, K_{ATP} channel openers shorten the action potential duration (and QT interval), reduce transmural dispersion of repolarization, and suppress EADs and DADs induced in patients with LQT1. Thus K_{ATP} channel openers can potentially prevent spontaneous torsades de pointes when congenital or acquired LQTS is secondary to reduced I_{Kr} or I_{Ks} . K_{ATP} channel openers may be useful in simulating ischemic preconditioning and may be protective in the setting of acute ischemia.

I_{KATP} blockers (e.g., sulfonylureas and various antiarrhythmic drugs) prevent the shortening of the action potential duration and can potentially prevent VF during myocardial ischemia. Nonetheless, they can also be arrhythmogenic. Moreover, because K_{ATP} channels are present

in pancreatic β cells and vascular smooth muscle, I_{KATP} blockers can produce hypoglycemia and coronary vasoconstriction, effects that may preclude their potential benefit as antiarrhythmic agents.

On the other hand, cardioselective I_{KATP} blockers (clamikalant, HMR 1098) inhibited hypoxia-induced shortening of the action potential duration and prevented VF induced by coronary artery occlusion in postinfarction conscious dogs at doses that had no effect on insulin release, blood pressure, or coronary blood flow. Thus these drugs may represent a new therapeutic approach to the treatment of ventricular arrhythmias in patients with coronary heart disease.

It is still unclear whether the opening of K_{ATP} channels has completely proarrhythmic or antiarrhythmic effects. Increased K^+ conductance should stabilize the E_m during ischemic injury and reduce the extent of infarct and ectopic pacemaker activity. On the other hand, K_{ATP} channel opening accelerates repolarization of the action potential, possibly promoting reentry.

Inherited Channelopathies

Gain-of-function mutations in *KCNJ8* (Kir6.1) and *ABCC9* (SUR2A) have been linked to J wave syndromes (Brugada and early repolarization syndromes). K_{ATP} channel-pore polymorphisms have also been linked to SCD.¹⁷

Mutations in *ABCC9* resulting in reduced intrinsic channel ATPase activity, metabolic sensing deficit, and dysfunctional K_{ATP} channels have been found in patients with idiopathic dilated cardiomyopathy and rhythm disturbances. These mutations confer susceptibility to Ca^{2+} -dependent maladaptive remodeling, progressing to cardiomyopathy and congestive heart failure. In addition, a loss-of-function *ABCC9* mutation has been linked to predisposition to adrenergic AF.

Gain- and loss-of-function mutations in *KCNJ11* (Kir6.2) and *ABCC8* (SUR1), which encode the predominant K_{ATP} channel subunits in pancreatic cells and in neurons, have now been identified as causal in human neonatal diabetes mellitus and congenital hyperinsulinism, respectively. Although cardiac K_{ATP} channels (Kir6.2/SUR2A) have the same Kir6.2 subunit as that in pancreatic K_{ATP} channels (Kir6.2/SUR1), there are no reports of any cardiac abnormalities in patients with neonatal diabetes mellitus; this finding suggests that factors other than nucleotide sensitivity play an important role.³⁰

More recently, gain-of-function mutations in *KCNJ8* (Kir6.1) and *ABCC9* (SUR2A) have been linked to Cantu syndrome (hypertrichosis-osteochondrodysplasia-cardiomegaly syndrome), a rare multiorgan disease characterized by multiple cardiovascular abnormalities (cardiac enlargement, ventricular hypertrophy, pericardial effusion, pulmonary hypertension secondary to partial pulmonary venous obstruction, patent ductus arteriosus, and bicuspid aortic valves with and without stenosis). In addition, these patients typically exhibit congenital hypertrichosis, distinctive acromegaly facial appearance (including broad nasal bridge, wide mouth with full lips, and macroglossia), and skeletal abnormalities (thickening of the calvaria, broad ribs, scoliosis, and flaring of the metaphyses). Of note, K_{ATP} channel openers, such as diazoxide and minoxidil, can also result in side effects such as hypertrichosis, pericardial effusion, edema, and even coarsening of the facial features.³⁰

Acquired Diseases

Metabolic dysregulation of I_{KATP} created by disease-induced structural remodeling appears to contribute to the dysfunction of heart failure.

The effects of Kir6.2 modulation in AF have not extensively been studied. However, evidence indicates a reduction of I_{KATP} in patients with chronic AF, a finding suggesting that regulation of this current may not contribute importantly to AF-related ionic remodeling.

Two-Pore Potassium Channels

Structure and Physiology

K_{2P} channels are composed of four transmembrane domains and two pore-forming P loops arranged in tandem, one between the first and second transmembrane domains and the other between the third and fourth domains (see Fig. 2.4). The presence of two pores enables K_{2P} channels to form homodimers or heterodimers instead of tetramers like other K^+ channels.¹⁶

K_{2P} channels are characterized by their lack of voltage sensitivity, their open state at all membrane potentials, and their regulation by numerous chemical and physical stimuli (such as pH, oxygen, phospholipids, neurotransmitters, G protein-coupled receptors, temperature, and stretch). These features allow these channels to play a role in regulating membrane potential and excitability in various cell types under a range of physiological and pathological situations.

Based on their functional properties, K_{2P} channels are classified into six different subfamilies: (1) two-pore domain in a weakly Kir channel (TWIK); (2) TWIK-related K^+ channel (TREK); (3) TWIK-related acid-sensitive K^+ channel (TASK); (4) TWIK-related alkaline-sensitive K^+ channel (TALK); (5) tandem pore domain halothane-inhibited K^+ channel (THIK); and (6) TRESK TWIK-related spinal cord K^+ channel (TRESK).

TASK channels exhibit sensitivity to variations in extracellular pH over a narrow physiological range. TASK-1 (*KCNK3*) and TASK-3 (*KCNK9*) subunits are functional when associated as homodimers or heterodimers. TASK channels display strong basal currents with very fast activation and inactivation kinetics.

TREK channels, which comprise TREK-1 (*KCNK2*), TREK-2 (*KCNK10*), and TRAAK (*KCNK4*), display low basal activity, but are stimulated by stretch of the cell membrane, lysophospholipids, and arachidonic acid and are inactivated by hypo osmolarity and phosphorylation by PKA and PKC.

Several members of the K_{2P} channel family are expressed in the heart and in the systemic or pulmonary circulations, and some contribute to background K^+ currents and the control of E_m in vascular smooth muscle cells. Of the 15 known different K_{2P} α subunits, TWIK-1 ($K_{2P}1.1$, encoded by *KCNK1*); TASK-1 ($K_{2P}3.1$, encoded by *KCNK3*); TASK-3 ($K_{2P}9.1$, encoded by *KCNK9*); TALK-2 ($K_{2P}17.1$, encoded by *KCNK17*) channels are found in human heart and are recognized to play a role in cardiac electrophysiology and some inherited forms of arrhythmias. Evidence suggest a role for TASK-1 in atrial repolarization and for TALK-2 in AVN conduction.^{16,20}

Function

There is clear evidence for TREK-1 and TASK-1 in the heart, and these channels likely modulate cardiac action potential duration through their regulation by stretch, polyunsaturated fatty acids, pH, and neurotransmitters. TREK-1 may also have a critical role in mediating the vasodilator response of resistance arteries to polyunsaturated fatty acids, thus contributing to their protective effect on the cardiovascular system. TASK-1, on the other hand, is a strong candidate for a role in hypoxic vasoconstriction of pulmonary arteries.

In working atrial and ventricular myocytes, background K^+ currents are crucial for stabilizing the E_m at a hyperpolarized value toward the K^+ equilibrium potential (E_K) and regulating action potential duration in various physiological and pathological conditions. The background current is mainly carried by inward rectifier channels (including I_{K1} , $I_{K_{ACH}}$, and $I_{K_{ATP}}$). Several K_{2P} channels have been proposed to contribute to the cardiac background or “leak” K^+ current through all phases of the cardiac action potential, thereby stabilizing the resting potential near the equilibrium potential of K^+ during phase 4, ensuring the

availability of Na^+ channels during phase 0 and facilitating repolarization during phase 1 to 3 of the action potential. Among them, TREK-1 and TASK-1 have been the most extensively studied.¹⁶

TREK-1, as an outwardly rectifying current, can potentially participate in balancing the E_m and action potential duration. Indeed, on a beat-to-beat basis, it could be involved in a negative feedback loop, hyperpolarizing the E_m in response to a stretch stimulus following the stretch activation of nonselective cation channels. The expression of TREK-1 appears to be nonuniform in the heart, with stronger TREK-1 mRNA expression in endocardial cells compared with epicardial cells. This finding possibly reflects different amounts of stretch experienced by muscle cells in different parts of the ventricular wall, leading to differential mechanoelectrical feedback and thereby reducing action potential repolarization in areas of the myocardium where conduction velocity is slower. Mechanoelectric feedback following an increase in atrial volume may be arrhythmogenic, changing the shape of the action potential. Physiological evidence of the direct involvement of TREK-1 current in mechanoelectric feedback in the heart is still to be provided.

Pharmacology

Data are limited regarding the pharmacology of K_{2P} channels. Theoretically, blockade of K_{2P} channels is expected to prolong action potential duration; however, whether K_{2P} channels could be promising antiarrhythmic drug targets remains to be investigated. Human cardiac $K_{2P}3.1$ (TASK-1) channels appear to be blocked by amiodarone. Other antiarrhythmic drugs, including mexiletine, propafenone, carvedilol, and dronedarone, also block TASK-1 at high therapeutic plasma concentration, indicating a possible contribution to their therapeutic effect.²⁰

Inherited Channelopathies

Mutations in *KCNK3* (encoding $K_{2P}3.1$ channels) resulting in attenuation of the TASK-1 current have been linked to familial AF.

Acquired Diseases

TREK-1 activity may have some importance in pathological conditions such as ischemia, when released purinergic agonists such as ADP and ATP lead to arachidonic acid production. Activation of TREK-1 by ATP during ischemia may contribute to electrophysiological disturbances in the ventricular wall. As a stretch-activated K^+ channel in atrial cells, TREK-1 could additionally be involved in regulating the release of atrial natriuretic peptide, which is released by a stretch-induced increase in intracellular Ca^{2+} concentration. Further work will be necessary to clarify the possible role of TREK or other stretch-dependent channels in the pathological heart.

Small-Conductance Calcium-Activated Potassium Channels

Structure and Physiology

Calcium-activated K^+ channels (KCa) are categorized into three subfamilies according to their single-channel K^+ conductance properties: big-conductance (BK, $KCa1.1$), intermediate-conductance (IK, $KCa3.1$), and small-conductance (SK, $KCa2.x$). To date, only small-conductance channels have been identified as functional in the cell membranes of cardiac myocytes.¹⁶

The subfamily of SK channels consists of three members with differential sensitivity to apamin: SK1 (or $KCa2.1$ encoded by *KCNN1*) with the least sensitivity; SK2 (or $KCa2.2$ encoded by *KCNN2*) with the highest sensitivity; and SK3 (or $KCa2.3$ encoded by *KCNN3*) with intermediate sensitivity.³²

Four α subunits ($KCa2.1$, $KCa2.2$, or $KCa2.3$) coassemble to form a functional homotetrameric or heterotetrameric SK channel. Each α

subunit consists of six transmembrane domains and one pore-forming loop between the fifth and sixth domains responsible for K^+ selectivity. Unlike K_v channels, the transmembrane segment S4 in the SK α subunit is uncharged. Also, SK channels do not coassemble with β subunits.

SK channels are activated by submicromolar concentrations of cytoplasmic Ca^{2+} . The Ca^{2+} sensitivity is ascribed to the association with calmodulin, which is constitutively bound to the proximal C-terminus of each α subunit and mediates gating in response to Ca^{2+} binding. SK channels play an important role in linking fluctuations in intracellular Ca^{2+} concentration with membrane K^+ conductance. Like in vascular smooth muscle, the physiologic function of SK channels in the heart is probably to limit excessive Ca^{2+} entry.¹⁶

The SK channel-mediated current (ISK or ISK,Ca) shows inward rectification, thereby limiting the physiological relevant outward current branch. Similar to the classic inward-rectifier K^+ currents, divalent cations such as Ca^{2+} or Mg^{2+} may account for this inward rectification.

Function

SK channels are highly expressed in a range of tissues including vascular endothelium, smooth and skeletal muscle, and neural tissue. Recent evidence suggests that SK channels are abundantly expressed in the atrium, while ventricular expression is relatively scarce. The three subtypes of SK channels display variable spatial distribution; SK1 and SK2 are predominantly expressed in the atrium, while SK3 is equally expressed in the atrium and the ventricle. However, the heterogeneous expression of SK channels in the heart is not completely defined.

Owing to their predominant expression in the atria, SK channels are attributed with atrial electrophysiology and have been proposed to play a role in the pathophysiology of AF. However, although multiple studies have reported that SK channels are important mediators of proarrhythmogenic electrical remodeling in the atria, the role of atrial SK channels in AF patients remains controversial; both ISK upregulation and downregulation have been reported in patients with persistent and permanent AF.^{16,32}

In the ventricles, SK channels do not appear to contribute significantly to repolarization under normal physiological circumstances; however, SK channels have been implicated as potentially important mediators of ventricular repolarization in failing hearts. ISK is upregulated in patients with heart failure, which can potentially increase ventricular repolarization reserve and provide an antiarrhythmic benefit.

Pharmacology

SK channels are selectively blocked by apamin (the active peptide neurotoxin in bee venom). The highly selective blockade by apamin is the signature of SK channels that enables verification of the molecular identity of SK channels in mammalian brain. Several other peptides from scorpion venom (such as scyllatoxin, tamapin, and BmSKTx1) block SK channels.^{24,32,33}

SK channels represent potentially attractive therapeutic targets for AF. The preferential atrial expression of SK channels may offer a unique therapeutic strategy to target atria without interfering with ventricular function. However, while some SK channel-modulating drugs in animal models have been demonstrated to suppress AF, others are associated with a negligible antiarrhythmic or indeed proarrhythmogenic effect, especially in the setting of heart failure.³³ Currently there is no general consensus of whether block of SK channels provides protection against or facilitates atrial or ventricular arrhythmias.²⁰

Regulation

SK channels are unique in that they are insensitive to membrane voltage and are gated solely by changes in intracellular Ca^{2+} . Calmodulin binds to a domain within the C-terminus of the SK channels. Binding of Ca^{2+}

to calmodulin results in changes in the conformation of the channels leading to channel activation. Calmodulin not only is essential for Ca^{2+} sensitivity but also is critical to the trafficking and cell surface expression of SK channels.³²

In addition to calmodulin, α -actinin2, filamin A, and myosin light chain-2 appear to play a role in the gating, regulation, and membrane trafficking of the SK channels in cardiomyocytes.³²

Inherited Channelopathies

Genome-wide association analysis revealed an association between single nucleotide polymorphism in *KCNN3* with lone AF.³²

Acquired Diseases

Both upregulation and downregulation of SK channels and ISK have been reported in patients with chronic AF, and the exact role of these channels in atrial remodeling and the pathophysiology of AF remains debated. ISK is upregulated in the failing heart, which could potentially enhance ventricular repolarization reserve and reduce the risk of DADs and triggered activity (eFig. 2.1).²⁰

CALCIUM CHANNELS

Structure and Physiology

Functional voltage-gated Ca^{2+} channels (Ca_v) are composed of pore-forming α_1 subunit proteins, encoded by the *CACNA1x* genes, of which there are 10 isoforms in the mammalian genome. Based on amino acid sequence similarity, $Ca_v\alpha_1$ channels are divided into three subfamilies: Ca_v1 , Ca_v2 , and Ca_v3 .

The Ca_v1 subfamily conducts the L-type Ca^{2+} current and includes four isoforms: $Ca_v1.1$ (α_1S), $Ca_v1.2$ (α_1C), $Ca_v1.3$ (α_1D), and $Ca_v1.4$ (α_1F), encoded by *CACNA1S*, *-C*, *-D*, and *-F*, respectively. Tissue expression of $Ca_v1.1$ and $Ca_v1.4$ is more restricted than that of $Ca_v1.2$ and $Ca_v1.3$. $Ca_v1.1$ is mainly expressed in skeletal muscle, while $Ca_v1.4$ is primarily restricted to the retina. $Ca_v1.2$ is the main isoform in cardiac muscle, and is also present in smooth muscle cells, secretory tissue, and the nervous system. $Ca_v1.3$ plays a major role in sinoatrial node tissue, and in the auditory system, and is also present in the brain. Both isoforms ($Ca_v1.2$ and $Ca_v1.3$) are often even expressed in the same cell, such as in neurons, adrenal chromaffin cells, and sinoatrial node and atrial cardiomyocytes.³⁴

The Ca_v2 subfamily conducts the P/Q-, N-, and R-type Ca^{2+} currents and includes three isoforms: $Ca_v2.1$ (α_1A , also termed P/Q-type), $Ca_v2.2$ (α_1B , also termed N-type), and $Ca_v1.2$ (α_1E , also termed R-type), encoded by *CACNA1A*, *-B*, and *-E*, respectively. The $Ca_v2.x$ channels are mainly expressed in the nervous system.³⁴

The Ca_v3 subfamily conducts the T-type Ca^{2+} current and includes three isoforms: $Ca_v3.1$ (α_1G), $Ca_v3.2$ (α_1H), and $Ca_v3.3$ (α_1I), encoded by *CACNA1G*, *-H*, and *-I*, respectively. The Ca_v3 channels are extensively distributed in neurons and other excitable cells. They have important roles in neuronal and cardiac excitability and in cardiac and neuronal pacemaker activity.³⁴

Although the α_1 subunit ($Ca_v\alpha_1$) is the principal component of voltage-gated Ca^{2+} channels and is responsible for their unique biophysical and pharmacological properties, a functional Ca^{2+} channel requires coassembly of the α_1 subunit with auxiliary subunits (β subunit and $\alpha_2\delta$ subunits; Fig. 2.9).³⁵ These accessory subunits enhance the expression of the α_1 subunit and modify its properties.

Both the Ca_v1 and Ca_v2 subfamilies are able to form a heteromeric complex, coassembling with one of four β subunits ($Ca_\beta1$ – β_4 , encoded by *CACNB1*–*4*), and one of four $\alpha_2\delta$ subunits (encoded by *CACNA2D1*–*4*). For the Ca_v3 channels, the α_1 subunits can form functional channels alone, but may also associate with other proteins.

Fig. 2.9 Membrane Topology and Structural Organization of the Subunits of the Cardiac L-Type Calcium Channel. The α_1 is the pore-forming subunit that contains voltage-sensing machinery and the binding sites of channel blockers. The α_1 subunit contains four homologous domains (I to IV), each containing six transmembrane helices (S1 to S6). The $\alpha_2\delta$ and β subunits enhance expression and modulate the voltage dependence and gating kinetics of the channel. (Modified from Gurkoff G, Shahlaie K, Lyeth B, Berman R. Voltage-gated calcium channel antagonists and traumatic brain injury. *Pharmaceuticals*. 2013;6:788–812.)

A γ subunit also forms part of the skeletal muscle Ca^{2+} channel complex. Eight γ subunit isoforms (γ_1 – γ_8 , encoded by *CACNG1*–*8*) have been identified. Only γ_4 , γ_6 , γ_7 , and γ_8 are expressed in human heart. However, no γ subunits have been shown to form an integral part of cardiac or neuronal Ca^{2+} channels.

For some Ca_v1 and Ca_v2 channels, the tight binding of calmodulin to an isoleucine-glutamine domain (the so-called “IQ” motif) in their C-terminal tail allows calmodulin to be considered as a quasi-subunit. Several other proteins interact with the channel complex, including kinases, phosphatases, scaffold proteins, caveolin-3, among others.

The α_1 Subunit

The α_1 subunit ($\text{Ca}_v\alpha_1$) has a structure similar to that of the Na^+ channel: four homologous domains (I to IV), each consisting of six transmembrane segments (S1 to S6). The S5 and S6 segments and the membrane-associated pore loop (P loop) between them form the central pore through which ions flow down their electrochemical gradient. The P loop contains four negatively charged glutamate residues (EEEE) that are required for the Ca^{2+} selectivity of the channel. S4 in each homologous domain contains a highly conserved positively charged residue (arginine or lysine) at every third or fourth position. This segment serves as the voltage sensor for gating.

The $\alpha_1\text{C}$ subunit is the main and largest component of Ca_v and it dictates the principal biophysical and pharmacological properties of these channels because it harbors the ion-selective pore, voltage sensor, gating apparatus, and the majority of drug- and toxin-binding sites.

The β Subunit

The β subunit ($\text{Ca}_v\beta_1$, encoded by the *CACNB* gene) is entirely intracellular and is tightly bound to a highly conserved motif in the cytoplasmic linker between domains I and II of the $\alpha_1\text{C}$ subunit (termed the α -interacting domain, AID). Coexpression of the β subunit modulates the biophysical properties of the $\alpha_1\text{C}$ subunit. The β subunit has a prominent role in channel expression, trafficking, and regulation. Sites possible for phosphorylation by various protein kinases (PKA, PKC, protein kinase G [PKG]) have been identified in these subunits. The β subunits are also involved in channel regulation by β -adrenergic stimulation and in response to the changes of the pH of the cell. In addition, the β subunit can dramatically enhance Ca^{2+} current amplitude, change the voltage dependence and kinetics of channel activation and inactivation, and alter pharmacological properties of the channel.

The $\alpha_2\delta$ Subunit

The α_2 and δ proteins are encoded by a single mRNA; the mature forms of the $\alpha_2\delta$ subunits are derived by posttranslational proteolytic cleavage of α_2 and δ , but they remain associated through a disulfide bond. The α_2 subunit is completely extracellular, whereas the δ subunit has a single membrane-spanning segment with a very short intracellular part that anchors the $\alpha_2\delta$ subunit complex to the $\alpha_1\text{C}$ subunit.

The $\alpha_2\delta$ subunit complex has less influence on channel function than the β subunit. The $\alpha_2\delta$ subunit slightly increases Ca^{2+} current amplitude and accelerates channel inactivation and can change the

properties of Ca^{2+} channel activation. It can also affect channel density trafficking.

The γ Subunit

The γ subunit is composed of four transmembrane segments and intracellular N- and C-termini. The γ subunits have variable effects on channel function, depending on the partnered $\text{Ca}_v\alpha_1$ and $\text{Ca}_v\beta$ subunits.

Cardiac L-Type Calcium Current

Structure and Physiology

In cardiac muscle, two types of voltage-dependent Ca^{2+} channels, the L-type and the T-type, transport Ca^{2+} into the cells. The L-type channel (L for long-lasting because of its slow kinetics of current decay as compared with Na^+ channels) is found in all cardiac cell types. The T-type channel (T for tiny and transient) is found principally in pacemaker, atrial, and Purkinje cells. The term “ Ca^{2+} channels” is used to refer to the L-type channel.

Cardiac L-type Ca^{2+} channels are composed of four polypeptide subunits (α_1 , β , α_2 , δ) and form a heterotetrameric complex. Both $\text{Ca}_v1.2$ ($\alpha_1\text{C}$ encoded by the *CACNA1C*) and $\text{Ca}_v1.3$ ($\alpha_1\text{D}$ encoded by the *CACNA1D*) isoforms are expressed in the heart, but their contribution to L-type current (I_{CaL}) varies in different regions.³⁶

L-type Ca^{2+} channels are characterized by a large single channel conductance. The channels are closed at the resting potential, but they activate on depolarization to potentials positive to -40 mV. I_{CaL} peaks at 0 to $+10$ mV, and tends to reverse at $+60$ to $+70$ mV, following a bell-shaped current-voltage relationship.

Although I_{CaL} is normally activated during phase 0 by the regenerative depolarization caused by the fast I_{Na} , I_{CaL} is much smaller than the peak I_{Na} . In addition, the amplitude of I_{CaL} is not maximal near the action potential peak because of the time-dependent nature of I_{CaL} activation as well as the low driving force ($E_m - E_{\text{Ca}}$, where E_{Ca} is reversal potential of a cardiac Ca^{2+} channel) for I_{CaL} .

The decay of I_{CaL} during depolarization (i.e., time-dependent inactivation) is very slow and depends on two mechanisms: voltage-dependent inactivation and Ca^{2+} -dependent inactivation. These two mechanisms control Ca^{2+} influx into cardiomyocytes and hence regulate signal transduction to sarcoplasmic reticulum Ca^{2+} channels (ryanodine receptor 2 [RyR2]) and ensure normal contraction and relaxation of the heart.

Fast Ca^{2+} -dependent inactivation serves as a negative feedback for Ca^{2+} to limit further Ca^{2+} entry via L-type Ca^{2+} channels. The slow voltage-dependent inactivation (induced by membrane depolarization) prevents a premature rise in I_{CaL} when intracellular Ca^{2+} concentration decreases and Ca^{2+} -dependent inactivation terminates during maintained depolarization. Although still under dispute, the relative contribution of Ca^{2+} -dependent inactivation to total inactivation of I_{CaL} appears to be greater at negative potentials when voltage-dependent inactivation, which typically exhibits a U-shaped availability curve, is weak. After β -adrenergic stimulation, Ca^{2+} -dependent inactivation becomes the main inactivation mechanism as a result of a slowing down of voltage-dependent inactivation.³⁵

The Ca^{2+} -dependent inactivation mechanism depends primarily on Ca^{2+} released from the sarcoplasmic reticulum. The Ca^{2+} -binding protein calmodulin functions as a critical sensor mediating Ca^{2+} -induced inactivation of L-type Ca^{2+} channels. Calmodulin binds to two $\alpha_1\text{C}$ subunit amino acid sequences (called domains L and K). When local intracellular Ca^{2+} concentration increases (secondary to influx Ca^{2+} via I_{CaL} , as well as Ca^{2+} -induced Ca^{2+} release from the sarcoplasmic reticulum), more Ca^{2+} ions bind to calmodulin, which harbors four Ca^{2+} -binding sites. When saturated with Ca^{2+} , conformational change of both calmodulin and $\alpha_1\text{C}$ subunit leads to blockage of the channel pore.

Voltage steady-state activation and inactivation are sigmoidal, with an activation range over -40 to $+10$ mV (with a half-activation potential near -15 mV) and a half-inactivation potential near -35 mV. However, a relief of inactivation for voltages positive to 0 mV leads to a U-shaped voltage curve for steady-state inactivation. Overlap of the steady-state voltage-dependent inactivation and activation relations defines a window current near the action potential plateau, within which transitions from closed and open states can occur that may participate in action potential repolarization and may play a major role in the initiation of EADs.

After inactivation, the transition of Ca^{2+} channels from the inactivated to the closed resting state (i.e., recovery from inactivation [reactivation, restoration, or repriming]) is also Ca^{2+} and voltage dependent. Reduction of intracellular Ca^{2+} concentration in the immediate vicinity of the channel allows recovery from Ca^{2+} -dependent inactivation. Acceleration of Ca^{2+} channel reactivation, as may occur secondary to reuptake of Ca^{2+} by the sarcoplasmic reticulum during prolonged depolarization, can result in the recovery from Ca^{2+} -dependent inactivation and enable secondary depolarization. This leads to instability of the cell E_m during repolarization and may be the basis for the EADs that are capable of initiating torsades de pointes.

Voltage-dependent recovery of I_{CaL} from inactivation between action potentials is slow at low (depolarized) E_m , and it becomes very fast as the action potential repolarization is nearly complete. As a consequence, I_{CaL} declines in response to repetitive stimulation at a partially depolarized E_m between pulses (resulting from Ca^{2+} channel incomplete recovery from inactivation), and a negative staircase of contractility is observed.

In contrast, at normal resting membrane potentials, recovery of I_{CaL} from inactivation is fast, and I_{CaL} can increase progressively during repetitive stimulation. This positive staircase or rate-dependent potentiation of contractility is Ca^{2+} dependent and likely is the result of diminished Ca^{2+} -dependent inactivation at frequencies with less sarcoplasmic reticulum Ca^{2+} release. In addition, similar to Ca^{2+} -dependent inactivation, Ca^{2+} -dependent facilitation requires high-affinity binding of calmodulin to the C-terminal tail of the $\text{Ca}_v1.2$ channel and can be facilitated by calmodulin kinase II-dependent phosphorylation. Calmodulin kinase II is a Ca^{2+} /calmodulin-dependent serine/threonine kinase that is activated by low intracellular Ca^{2+} concentration. The facilitatory effect of Ca^{2+} entry on subsequent I_{CaL} is distinct from, but coexistent with, Ca^{2+} -dependent inactivation.

Function

Both $\text{Ca}_v1.2$ and $\text{Ca}_v1.3$ isoforms are expressed in the heart. In the working myocardium, the $\text{Ca}_v1.2$ channels predominate, with no (ventricular myocytes) or minimal (atrial myocytes) expression of $\text{Ca}_v1.3$. In contrast, $\text{Ca}_v1.3$ is the predominant isoform in the sinus node and AVN, and plays an important role in pacemaking function.³⁶

In atrial and ventricular cardiomyocytes, $\text{Ca}_v1.2$ channels trigger contraction. I_{CaL} is activated by membrane depolarization, is largely responsible for the action potential plateau, and is a major determinant of the duration of the plateau phase and hence of the action potential duration and refractoriness. I_{CaL} also links membrane depolarization to myocardial contraction and constitutes the dominant factor in mediating positive inotropy in cardiac tissue.

L-type Ca^{2+} channels are the principal portal of entry of Ca^{2+} into the cells during depolarization. Ca^{2+} influx during the action potential plateau triggers more massive Ca^{2+} release (Ca^{2+} transients) from the sarcoplasmic reticulum into the cytosol via activation of Ca^{2+} -release channels (e.g., RyR2). This amplifying process, termed Ca^{2+} -induced Ca^{2+} release (CICR), causes a rapid increase in intracellular Ca^{2+} concentration (from approximately 100 nM to approximately 1 μM) to a

level required for optimal binding of Ca^{2+} to troponin C and induction of contraction. Most of the L-type Ca^{2+} channels in the adult myocyte are localized in the transverse tubules (T tubules) facing the sarcoplasmic reticulum junction and the RyR2, organized as a “complex” that ensures coordinated Ca^{2+} release during excitation-contraction coupling.

Cytosolic Ca^{2+} concentration decreases during diastole: contraction is followed by Ca^{2+} release from troponin C and its reuptake by the sarcoplasmic reticulum via activation of the sarcoplasmic reticulum Ca^{2+} -ATPase Ca^{2+} pump, in addition to extrusion across the sarcolemma via the Na^{+} - Ca^{2+} exchanger. Intracellular Ca^{2+} -dependent inactivation limits Ca^{2+} influx during action potential.

For maintenance of intracellular Ca^{2+} homeostasis and balanced cardiac activity, Ca^{2+} influx into cytoplasm via I_{CaL} has to be terminated. This is achieved by Ca^{2+} -dependent inactivation of I_{CaL} . This inactivation serves as a negative feedback mechanism for regulating Ca^{2+} entry into the cell and as a physiological safety mechanism against a harmful Ca^{2+} overload in the cell, which can cause both arrhythmias and cell death. Ca^{2+} -dependent inactivation is also a major determinant of action potential duration, and it ensures that contraction and relaxation cycles of the heart muscle fiber are coordinated. A failure to deactivate I_{CaL} completely may possibly be an essential mechanism underlying EADs caused by suppression of the K^{+} delayed rectifier currents.³⁶

Inhibition of $\alpha 1\text{C}$ subunit binding to calmodulin eliminates Ca^{2+} -dependent inactivation, thus promoting Ca^{2+} -dependent facilitation, which contributes to a force-frequency relationship in the heart.

In addition, I_{CaL} is responsible for the upstroke (phase 0) of slow response action potentials (in pacemaking cardiomyocytes and regions of depressed resting E_m) and contributes to physiological frequency regulation in the sinus node.

In sinus node cells, both $\text{Ca}_v1.2$ and $\text{Ca}_v1.3$ channel isoforms are required for proper function. $\text{Ca}_v1.2$ support the sinus node action potential. $\text{Ca}_v1.3$ channels activate at more negative threshold (activation) potential than $\text{Ca}_v1.2$. This property facilitates pacemaking function, since $\text{Ca}_v1.3$ channels are activated earlier during the diastolic depolarization phase. Further, $\text{Ca}_v1.3$ closely co-localizes with sarcomeric RyRs, which may allow it to contribute to RyR-mediated Ca^{2+} release during diastolic depolarization. $\text{Ca}_v1.3$ is also the prominent L-type channel in AVN cells and contributes to AVN conduction and pacemaking.³⁶

Regulation

Phosphorylation of the pore-forming $\alpha 1$ subunits by different kinases is one of the most important pathways to change the activity of the L-type Ca^{2+} channel. Phosphorylation by PKA is the main mechanism of Ca^{2+} channel activation, because it increases the probability and duration of the open state of the channels and consequently increases I_{CaL} .

Several different agonists (e.g., catecholamines, glucagon, histamine, serotonin) can activate PKA-mediated phosphorylation and activation of the L-type Ca^{2+} channel via an intracellular signaling cascade. Once one of these agonists binds to its receptor, receptor stimulation activates guanosine triphosphate (GTP)-binding protein (Gs), which activates adenylyl cyclase and in turn mediates the conversion of ATP into cAMP. The increased cAMP levels stimulate cAMP-dependent PKA phosphorylation of $\text{Ca}_v\alpha 1$ and result in an increase in I_{CaL} amplitude and a shift in activation to a more negative E_m . cAMP is degraded by cAMP phosphodiesterases, and the signaling cascade is then suppressed, limiting cAMP-dependent phosphorylation; in addition, the signaling cascade is terminated by serine/threonine phosphatases that remove a phosphate group from kinase-phosphorylated proteins.

The suppression of adenylyl cyclase activity is one of the most common pathways to interrupt PKA-dependent Ca^{2+} channel stimulation. Adenylyl cyclase is usually suppressed (and cAMP synthesis is blocked) by activation of Gi proteins. Stimulation of various Gi protein-coupled receptors (e.g., M2 muscarinic receptors, adenosine A1 receptors, opiates, and atrial natriuretic peptides) does not change basal I_{CaL} in most cases, but reduces I_{CaL} increased via stimulation of β -adrenergic receptors. Activation of phosphodiesterases is another way to reduce PKA-dependent channel phosphorylation. Phosphodiesterases hydrolyze cAMP and cyclic guanosine monophosphate (cGMP) and decrease their intracellular concentrations.

The physiological functions of cardiac L-type Ca^{2+} channels are under control of catecholamines of circulating and neurohumoral origin. The effects of adrenergic stimulation are exerted by phosphorylation of the L-type Ca^{2+} channel subunits by PKA, PKC, and PKG. $\beta 1$ -Adrenergic receptors couple exclusively to the Gs protein, thus producing a widespread increase in cAMP levels in the cell, whereas $\beta 2$ -adrenergic receptors couple to both Gs and Gi, thus producing a more localized activation of L-type Ca^{2+} channels.

The effect of PKC-mediated phosphorylation on I_{CaL} can be highly diverse. PKC can either increase or decrease I_{CaL} . Activation of Gq subunits by Gq protein-coupled receptors (e.g., α -adrenergic receptors, endothelin, angiotensin II, and muscarinic receptors) stimulates phospholipase C, which hydrolyzes PIP2 to inositol 1,4,5-triphosphate (InsP3) and diacylglycerol (DAG). DAG activates PKC, which, in turn, phosphorylates L-type Ca^{2+} channels. The mechanism of the effect of PKC on the activity of cardiac L-type Ca^{2+} channels is not exactly known. PKC phosphorylates the N-terminus of $\text{Ca}_v\alpha 1$, and the effect on the channel can be either stimulating or suppressive.

Activation of soluble guanylate cyclase (primarily by nitric oxide) results in the conversion of GTP into cGMP. cGMP activates PKG, which phosphorylates $\text{Ca}_v\alpha 1$, with a resulting inhibition of I_{CaL} . Besides direct phosphorylation of the L-type Ca^{2+} channel, it is also possible that PKG activates a protein phosphatase, which dephosphorylates the channel, or that cGMP activates phosphodiesterase 2, which reduces cAMP levels. Thus stimulation of I_{CaL} by PKA is inhibited. However, besides an inhibition of I_{CaL} , stimulatory effects of the PKG pathway have been shown.

I_{CaL} is blocked by several cations (such as Mg^{2+} , nickel [Ni^{2+}], zinc [Zn^{2+}]) and drugs (including dihydropyridines, phenylalkylamines, benzothiazepines). In addition, coexpression of the β -subunit increases I_{CaL} amplitude, accelerates the kinetics of Ca^{2+} channel activation, and alters pharmacological properties of the channel.

Pharmacology

Cardiac L-type Ca^{2+} channels are the targets for class IV antiarrhythmic drugs. The three classes of Ca^{2+} channel blockers include dihydropyridines (e.g., nifedipine, nicardipine, amlodipine, felodipine), phenylalkylamines (verapamil), and benzothiazepines (diltiazem). They all preferentially target the $\text{Ca}_v1.2$ channels that initiate excitation-contraction coupling in cardiac and vascular smooth muscle. Each drug type binds specifically to separate binding sites on the channel's $\alpha 1\text{C}$ subunit. The combined use of Ca^{2+} channel blockers can enhance or weaken the block effect because, at least in part, of the different binding sites for those drugs. It is noteworthy that increased extracellular Ca^{2+} concentrations inhibit the binding of phenylalkylamines and dihydropyridines to their receptors on $\text{Ca}_v\alpha 1\text{C}$.

Verapamil and diltiazem preferentially block open and inactivated states of the channel. Thus repeated opening of the channel pore in rapidly firing cells allows more rapid access of the drugs to their receptor site and increases the fraction of Ca^{2+} channels that are blocked. Hence these drugs cause use-dependent block of conduction in cells

with Ca^{2+} -dependent action potentials such as those in the sinus node and AVN. This explains their preferential effect on nodal tissue in paroxysmal SVT.

Dihydropyridines stabilize and induce inactivated channel states, and they likely act as gating modifiers rather than pore blockers. Those drugs exhibit high affinity to the inactivated channel state. Since the inactivated channel state is more prevalent in vascular smooth muscle, due to the depolarized resting membrane potential, dihydropyridines preferentially block $\text{Ca}_v1.2$ in vascular smooth muscle, leading to vasodilation. The kinetics of recovery from block is sufficiently fast that these drugs produce no significant cardiac effect.³⁷

Inherited Channelopathies

Long QT syndrome. Gain-of-function mutations of the *CACNA1C* gene encoding the $\alpha_1\text{C}$ subunit ($\text{Ca}_v1.2$) result in nearly complete elimination of voltage-dependent inactivation of $\text{Ca}_v1.2$ channels, thus leading to inappropriate continuation of the depolarizing I_{CaL} and lengthening the plateau phase of the action potential. The resultant sustained Ca^{2+} influx, action potential (and QT interval) prolongation, and Ca^{2+} overload promote EADs and DADs (Table 2.4). These mutations have been

linked to Timothy syndrome, a rare disease with QT interval prolongation (LQT8). Because the $\text{Ca}_v1.2$ is abundant in many tissues, patients with Timothy syndrome have many clinical manifestations, including congenital heart disease, autism, syndactyly, and immune deficiency. However, the exact pathophysiology of hypertrophic cardiomyopathy, congenital heart defects, and extracardiac manifestations of Timothy syndrome and their relation to *CACNA1C* mutations remain unclear.

Recently, multiple nonsyndromic LQTS-causative mutations in *CACNA1C* (nonsyndromic LQT8) were described in patients with isolated QT prolongation and propensity to ventricular arrhythmias in the absence of congenital heart defects and extracardiac manifestations that define Timothy syndrome.³⁸ Other *CACNA1C* mutations were found to cause cardiac-only Timothy syndrome (COTS), characterized by the concomitant but variably expressed phenotypes of LQTS (QT prolongation), hypertrophic cardiomyopathy, congenital heart defects, and SCD in the absence of any extracardiac symptoms.^{38,39}

Brugada syndrome. Approximately 13% of cases of the Brugada syndrome are attributable to loss-of-function mutations in the cardiac Ca^{2+} channel, resulting in a reduction of the depolarizing I_{CaL} . These include *CACNA1C* (which encodes $\text{Ca}_v1.2$), *CACNB2* (which encodes $\text{Ca}_v\beta_2$), and *CACNA2D1* (which encodes the $\alpha_2\delta$ subunit of $\text{Ca}_v1.2$). In this setting, the mechanism of Brugada syndrome involves a reduction of the depolarizing I_{CaL} .⁴⁰

Short QT syndrome. SQT4 is caused by mutations of the *CACNA1C* gene (encoding $\text{Ca}_v1.2$), SQT5 is caused by mutations of the *CACNB2* gene (encoding the $\text{Ca}_v\beta_2\text{b}$ subunit of $\text{Ca}_v1.2$), and SQT6 is caused by mutations of the *CACNA2D1* gene (encoding the $\alpha_2\delta_1$ subunit of $\text{Ca}_v1.2$). Loss-of-function mutations of those genes result in major attenuation in I_{CaL} amplitude, leading to shortening of the action potential duration.⁴¹

Early repolarization syndrome. Loss-of-function mutations in the $\alpha_1\text{C}$, β_2 , and $\alpha_2\delta$ subunits of the cardiac L-type Ca^{2+} channel (encoded respectively by the *CACNA1C*, *CACNB2*, *CACNA2D1* genes) have been reported in patients with early repolarization syndrome.

Acquired Diseases

Abnormalities in Ca^{2+} currents or intracellular Ca^{2+} transients in acquired diseases may induce both arrhythmia and contractile dysfunction. In AF, $\text{Ca}_v1.2$ mRNA and protein levels are downregulated, resulting in I_{CaL} reduction, which contributes to action potential shortening.

In heart failure, the membrane density of I_{CaL} channels is reduced. However, channel phosphorylation is increased, leading to reduced response to phosphorylating interventions and causing increased single channel open probability that compensates for the reductions in channel density. Despite unchanged I_{CaL} , sarcoplasmic reticulum Ca^{2+} transients are smaller and slower in heart failure, and they cause contractile dysfunction.

T-Type Calcium Current

Structure and Physiology

The cardiac T-type Ca^{2+} channel (originally called low-voltage-activated channels) is composed of a single α_{11} subunit. $\text{Ca}_v3.1$ ($\alpha_{1\text{G}}$ subunit encoded by *CACNA1G*) and $\text{Ca}_v3.2$ ($\alpha_{1\text{H}}$ subunit encoded by *CACNA1H*) isoforms are major candidates for the cardiac T-type Ca^{2+} channel. The structure of the $\alpha_{1\text{H}}$ and $\alpha_{1\text{G}}$ subunits is similar to that involved in the L-type Ca^{2+} channels. However, unlike L-type Ca^{2+} channels, T-type Ca^{2+} channels lack AID and IQ motifs, and do not require β subunits or calmodulin for appropriate function.

T-type Ca^{2+} channels can be distinguished from L-type channels on the basis of their distinctive gating and conductance properties. Compared with L-type Ca^{2+} channels, T-type channels have a smaller conductance and transient openings, generating small currents that quickly

TABLE 2.4 Inherited Channelopathies Related to Calcium Regulation

Clinical Phenotype	Gene	Protein	Functional Effect
Long QT Syndrome (LQTS)			
LQT8 (Timothy syndrome)	CACNA1C	$\text{Ca}_v1.2$	$\uparrow I_{\text{CaL}}$
LQT14	CALM1	Calmodulin 1	$\uparrow I_{\text{CaL}}$

I_{CaL} , L-type Ca^{2+} current.

decay (within 10s of milliseconds) because of inactivation. Also, T-type channels open at the significantly more negative E_m that overlaps the pacemaker potentials of sinus node cells. The threshold for activation of I_{CaT} is -70 to -60 mV, and I_{CaT} is fully activated at -30 to -10 mV at physiological Ca^{2+} concentration. Membrane depolarization also causes inactivation of I_{CaT} . The inactivation threshold is near -90 mV, with half-maximal inactivation at -60 mV. In contrast to L-type Ca^{2+} channels, T-type Ca^{2+} channels do not inactivate in a Ca^{2+} -dependent manner. The activation and steady-state inactivation overlap near the activation threshold (-60 to -30 mV), thus providing a constant inward current (a window current). This window component may help facilitate the slow diastolic depolarization in sinus node cells and contribute to automaticity.

Function

Ca_v3 channels conduct the T-type Ca^{2+} current (I_{CaT}), which is important in a wide variety of physiological functions, including neuronal firing, hormone secretion, smooth muscle contraction, cell proliferation of some cardiac tissues, and myoblast fusion. In the heart, T-type channels are abundant in sinus node pacemaker cells and Purkinje fibers of many species and are important for maintenance of pacemaker activity by setting the frequency of action potential firing.

T-type Ca^{2+} channels are functionally expressed in embryonic hearts, but they are almost undetectable or markedly reduced in postnatal ventricular myocytes, although some reports described substantial amplitude of I_{CaT} . In the adult heart, the largest I_{CaT} densities are seen in pacemaker cells located in the conduction system.

Because T-type Ca^{2+} channels are most prevalent in the conduction system in the adult heart and the activation range of I_{CaT} overlaps the pacemaker potential, it has been suggested that T-type Ca^{2+} channels play a role in generating pacemaker depolarization and contribute to automaticity. However, experimental evidence indicates that I_{CaT} is not a primary pacemaker current; rather, it can modify depolarization frequency to a small extent. Although organic T-type Ca^{2+} channel blockers (e.g., mibefradil) result in marked decrease in firing frequency of sinus node cells in clinical studies, the possibility that these blockers affect other ionic currents, including I_{CaL} , cannot be entirely excluded. Further studies are necessary to clarify the role of T-type Ca^{2+} channels in the human heart.

Pharmacology

Unlike L-type channels, T-type Ca^{2+} channels are relatively insensitive to dihydropyridines. Mibefradil preferentially block Ca_v3 , as compared with Ca_v2 , but is also capable of blocking several other ion channels, including Na^+ and K^+ channels.

Acquired Diseases

Interestingly, the T-type Ca^{2+} channels are reexpressed in atrial and ventricular myocytes in animal models under various pathological conditions such as cardiac hypertrophy, MI, and heart failure. These findings reflect a reversion to a fetal or neonatal pattern of gene expression, and I_{CaT} contributes to abnormal electrical activity and excitation-contraction coupling. It is possible that similar remodeling occurs in the hypertrophied human heart; however, to date, T-type Ca^{2+} channels have not been detected in normal or diseased human myocardial cells.

Furthermore, experimental evidence suggests that T-type Ca^{2+} channels can be of functional importance in arrhythmogenesis in cardiomyocytes in the pulmonary veins, which can initiate paroxysmal AF. I_{CaT} may directly and indirectly participate in pacemaker depolarization in sinoatrial and other regions of the heart, and this mechanism may become more important in failing hearts.

CARDIAC PACEMAKER CURRENT

Structure and Physiology

Channels responsible for the pacemaker current (I_f ; also called the funny current because it displays unusual gating properties) are named hyperpolarization-activated cyclic nucleotide-gated (HCN) channels. HCN channels are members of the voltage-gated cation channel superfamily and, based on sequence homology, are most closely related to the cyclic nucleotide-gated (CNG) channel and ether-a-go-go (EAG) K^+ channel families.

Four α -subunit isoforms are described (HCN1 to HCN4, encoded by *HCN1* to *HCN4*), which are preferentially expressed in sinus and AVN myocytes and Purkinje fibers. HCN isoforms differ in the extent of voltage-dependent gating and sensitivity to cAMP, and they have different relative rates of activation and deactivation, with HCN1 the fastest, HCN4 the slowest, and HCN2 and HCN3 intermediate. HCN4 is the isoform primarily expressed in the sinus node, AVN, and ventricular conducting system, but low levels of HCN1 and HCN2 have also been reported.⁴²

It is likely that the HCN channel is formed by the coassembly of four either identical (homotetramers) or nonidentical (heterotetramers) α subunits that create an ion-conducting pore. Each α subunit comprises six transmembrane segments (S1 to S6), with a voltage sensor domain in the S4 segment and a pore-forming region between S5 and S6 carrying the GYG triplet signature of K^+ -permeable channels. Their intracellular C-terminus contains cyclic nucleotide-binding domains, which enable direct cAMP binding. A potential auxiliary subunit of HCN channels is MiRP1 (encoded by *KCNE2*).⁴³

I_f is a mixed Na^+ - K^+ current, with a threefold higher selectivity for Na^+ than for K^+ . Despite the GYG amino acid motif, HCN channels are more permeable to Na^+ than K^+ ions. Unlike most voltage-gated channels, which are activated on membrane depolarization, HCN channels are activated on hyperpolarization. The HCN channel activates slowly on hyperpolarization (at voltages lower than approximately -40 to -45 mV) and inactivate slowly in a voltage-independent manner on depolarization. The speed of channel opening is strongly dependent on E_m and is faster at more negative potentials. I_f conducts an inward current during phases 3 and 4 of the action potential and may underlie slow membrane depolarization in cells with pacemaker activity (i.e., cells with I_f and little or no I_{K1}).

Function

I_f is a major player in both generation of spontaneous activity and rate control of cardiac pacemaker cells, and it is sometimes referred to as the “pacemaker current.”

HCN channels are deactivated during the action potential upstroke and the initial plateau phase of repolarization, but they begin to activate at the end of the action potential as repolarization brings the E_m to levels more negative than -40 to -50 mV, and they are fully activated at approximately -100 mV. Once activated, I_f depolarizes the membrane back toward a level at which the Ca^{2+} current activates to initiate the action potential. In its range of activation, which quite properly comprises the voltage range of diastolic depolarization in sinus node cells (approximately -40 to -65 mV), the current is inward, and its reversal occurs at approximately -10 to -20 mV. At the end of the repolarization phase of an action potential, because I_f activation occurs in the background of a decaying outward (K^+ time-dependent) current, current flow quickly shifts from outward to inward, giving rise to a sudden reversal of voltage change (from repolarizing to depolarizing) at the maximum diastolic potential. Hence I_f first opposes and then stops the repolarization process (at the maximum diastolic potential) and finally initiates the diastolic depolarization.⁴³

The I_f contribution terminates when, in the late part of diastolic depolarization, Ca^{2+} -dependent processes take over, and the threshold for L-type Ca^{2+} current activation and action potential firing is reached. Although deactivation of I_f at depolarized voltages is rapid, complete switch off of the current occurs only during the very early fraction of the action potential, which provides a brief time interval during which I_f carries an outward current at positive voltages.

I_f is not only involved in principal rhythm generation but also plays a key role in heart rate regulation. The degree of activation of I_f determines, at the end of an action potential, the steepness of phase 4 depolarization and hence the frequency of action potential firing. In addition, I_f represents a basic physiological mechanism mediating autonomic regulation of heart rate. I_f is regulated by intracellular cAMP and is thus activated and inhibited by β -adrenergic and muscarinic M2 receptor stimulation, respectively.

However, given the complexity of the cellular processes involved in rhythmic activity, exact quantification of the extent to which I_f and other mechanisms contribute to pacemaking is still a debated issue.

Regulation

The voltage dependence of I_f activation is regulated by cAMP direct binding to the cyclic nucleotide-binding domain in the HCN channel and not via phosphorylation-dependent activation mechanisms. Direct interaction of cAMP to the channel shifts the activation curve to more depolarized voltages and strongly accelerates channel activation kinetics. Sympathetic stimulation activates I_f and hence accelerates heart rate via β -adrenoceptor-triggered cAMP production, whereas low-level vagal stimulation lowers heart rate via inhibition of cAMP synthesis and an ensuing inhibition of I_f activity. High vagal tone most likely lowers the heart rate, mainly via the activation of I_{KACH} .

HCN channels are inhibited by increased intracellular acidity (e.g., during myocardial ischemia). Protons shift the activation of I_f to more hyperpolarized potentials and slow pacemaker activity.

Pharmacology

Given the key role of HCN channels in cardiac pacemaking, I_f has become a pharmacological target for the development of novel and more specific heart rate-reducing agents in patients with ischemic heart disease, systolic heart failure, and inappropriate sinus tachycardia. Whereas current heart rate-lowering drugs adversely affect cardiac contractility, selective I_f inhibition is believed to lower heart rate without impairing contractility. In the past, several agents inhibiting cardiac I_f were developed. Early drugs identified as pure negative chronotropic agents include zatebradine and cilobradine, which are derived from the L-type Ca^{2+} channel blocker verapamil.⁴³

Ivabradine is a selective inhibitor of I_f . Ivabradine blocks HCN4 and HCN1 channels by accessing the channels from their intracellular side and by exerting a use- and current-dependent block. Interestingly, ivabradine acts as open channel blocker in HCN4 (as in sinus nodal I_f), whereas block of HCN1 requires channels either to be closed or in a transitional state between an open and closed configuration. Unlike ivabradine, other HCN channel blockers are not specific enough for sinus nodal (mainly HCN4-mediated) I_f ; they also block neuronal HCN channels (I_h current) in several regions of the nervous system, and this has prevented their clinical utility. The principal action of all these substances is to reduce the frequency of pacemaker potentials in the sinus node by inducing a reduction of the diastolic depolarization slope.⁴⁴⁻⁴⁶

Ivabradine induces heart rate reduction without any modification in cardiac contractility and atrioventricular and intraventricular conduction times. Blockade of the I_f current induced by ivabradine is dose and heart rate dependent, resulting in greater effects during fast heart

rates and limiting the risk of symptomatic bradycardia. Clinical trials have demonstrated ivabradine to be an effective antianginal agent in patients with ischemic heart disease and to offer significant hemodynamic benefits in patients with systolic heart failure and higher baseline heart rates. Several smaller studies also suggest a potential benefit of ivabradine in the treatment of patients with inappropriate sinus tachycardia.⁴⁴⁻⁴⁷

Clonidine, an α_2 -adrenergic agonist, was shown to block sinus nodal I_f . Clonidine produces a shift in the voltage dependence of the channel by 10 to 20 mV to more hyperpolarizing potentials.

Inherited Channelopathies

Heterozygous loss-of-function *HCN4* mutations have been identified in individuals with familial sinus bradycardia AV block, early-onset AF, tachycardia-bradycardia syndrome. Also, severe bradycardia resulting from *HCN4* mutations can potentially result in QT prolongation and torsades de pointes or lead to accentuation or unmasking of the Brugada syndrome phenotype. HCN mutations slow channel activation kinetics or, when located in cyclic nucleotide-binding domains, abolish sensitivity of HCN channels to cAMP, thus attenuating I_f and reducing the speed of diastolic depolarization. Recently a gain-of-function mutation in *HCN4* was linked to familial inappropriate sinus tachycardia.^{48,49}

Acquired Diseases

HCN2/HCN4 expression is upregulated in the atria of patients with AF and in ventricular tissues in cardiac hypertrophy and congestive heart failure. This response may contribute to the arrhythmias observed in these disease states. Enhancement of I_f in these pathological conditions can potentially initiate arrhythmia by triggering spontaneous excitation of nonpacemaker cardiomyocytes.

SARCOPLASMIC RETICULUM CALCIUM RELEASE CHANNELS (RYANODINE RECEPTOR 2)

Structure and Physiology

The Ca^{2+} release channel is a macromolecular complex, formed by the cardiac ryanodine receptor isoform (RyR2, encoded by the *RYR2* gene) homotetramer and certain proteins localized on both the cytosolic and the luminal side of the sarcoplasmic reticulum membrane. Cardiac RyR2, by far the largest protein of the complex, operates as a Ca^{2+} -conducting channel. RyR2 channels are approximately 10 times larger than voltage-gated Ca^{2+} and Na^{+} channels.

Each RyR2 monomer contains a transmembrane domain, the pore-forming region that is composed of an even but still undetermined number (likely 6 to 8) of transmembrane segments. This domain encompasses only approximately 10% of the protein clustered at the C-terminus, but it has a critical functional role because it contains sequences that control RyR2 localization and oligomerization and is sufficient to form a functional Ca^{2+} release channel. The remaining 90% of the protein at the N-terminus comprises an enormous cytoplasmic domain that serves as a cytosolic scaffold that interacts with regulatory molecules (including Ca^{2+} , ATP) and proteins (including FKBP12.6, calmodulin). On the luminal (sarcoplasmic reticulum) side, RyR2 forms a part of a large quaternary complex with calsequestrin (CASQ2), triadin, and junctin. Together these four proteins form the core of the Ca^{2+} release channel complex (Fig. 2.10).⁵⁰

Cardiac RyR2 functions as a ligand-activated ion channel that activates (opens) on Ca^{2+} binding. However, the exact structural determinants of RyR gating are as yet unknown. RyR2 is normally closed at low cytosolic Ca^{2+} concentrations (approximately 100 to 200 nM) during diastole. At submicromolar cytosolic Ca^{2+} concentrations, Ca^{2+} binds to high-affinity binding sites on RyR2 and thus increases the open

Fig. 2.10 Three-Dimensional Map of Ryanodine Receptor (RyR) Assembly. The large gray structure shows a side view of the RyR homotetramer. In order to show the interactions between sarcoplasmic reticulum membrane-bound RyR and its associated proteins, the single particle cryo-electron microscope reconstruction map of rabbit RyR1 in the closed state at resolution of 10 Å was used. Location of each domain is labeled in red. D1–3 (white) and transmembrane assembly (TA) (brown) indicate the divergent region and transmembrane assembly domain, respectively. D2 is located in the groove hidden by domains 5 and 6. probability of the channel (two Ca^{2+} ions are required to open the RyR2 channel) and allows Ca^{2+} release from the sarcoplasmic reticulum into the cytosol.

The precise juxtaposition of the sarcolemmal specialized invaginations (known as T tubules) and sarcoplasmic reticulum forms specific junctional microdomains, creating a 10- to 12-nM gap, known as the dyadic cleft. RyR2s are assembled in a paracrystalline lattice in each dyad, containing 80 to 260 channels, where the RyR2 cytoplasmic region resides, and its transmembrane region spans the sarcoplasmic reticulum membrane to immerse the luminal portion into the sarcoplasmic reticulum Ca^{2+} store. Each array of RyR2s is faced by 10 to 25 L-type Ca^{2+} channels in the sarcolemmal T tubule. Hence each dyad constitutes a local Ca^{2+} signaling complex, or “couplon,” whereby these proteins are coordinately regulated via the changing concentrations of Ca^{2+} , Na^+ , and K^+ within the dyadic cleft.

After approximately 10 milliseconds of RyR2 channel opening, Ca^{2+} release from the sarcoplasmic reticulum terminates, and the Ca^{2+} spark signal starts to decay, mostly owing to diffusion of Ca^{2+} away from its source. RyR2 channel activity is maximal at cytosolic Ca^{2+} concentrations of approximately 10 μM . Elevating cytosolic Ca^{2+} concentrations beyond this point leads to a reduction in the open probability of the

channel, possibly because of Ca^{2+} binding to low-affinity inhibitory binding sites on the RyR2 channel.

Inactivation of Ca^{2+} release is not well understood. It is likely mediated by Ca^{2+} -induced inactivation of RyR2, thus extinguishing of CICR by stochastic attrition, or by Ca^{2+} depletion of the sarcoplasmic reticulum, or both.

RyR2 open probability increases by elevation of sarcoplasmic reticulum Ca^{2+} concentration. When levels of Ca^{2+} in the sarcoplasmic reticulum reach a critical threshold, spontaneous Ca^{2+} release (spillover) can occur even in the presence of normal channels (store overload–induced Ca^{2+} release [SOICR]). Ca^{2+} concentration in the sarcoplasmic reticulum is physiologically increased as an effect of adrenergic (sympathetic) stimulation.

Function

The RyR2 channels are an essential component of the excitation-contraction coupling and act as sentinels to the large sarcoplasmic reticulum Ca^{2+} store. Excitation-contraction coupling describes the physiological process of converting an electrical stimulus (action potential) to a mechanical response (muscle contraction). The contraction of a cardiac myocyte is governed primarily by intracellular Ca^{2+} concentration

(see Fig. 1.7). Ca^{2+} enters the cell during the plateau phase of the action potential through L-type Ca^{2+} channels that line the sarcolemmal T tubules. However, the rise in intracellular Ca^{2+} is small and not sufficient to induce contraction. Nonetheless, the small amount of Ca^{2+} entering the cell via I_{CaL} triggers a rapid mobilization of Ca^{2+} from the sarcoplasmic reticulum into the cytosol by opening the RyR2 channels in the CICR process. Approximately 75% of Ca^{2+} present in the cytoplasm during contraction is released from the sarcoplasmic reticulum. The close proximity of the RyR2 to the T tubule enables each L-type Ca^{2+} channel to activate 4 to 6 RyR2s and generate a Ca^{2+} spark. Ca^{2+} influx via I_{CaL} simultaneously activates approximately 10,000 to 20,000 couplons in each ventricular myocyte with every action potential. Such sophisticated coordination in opening and closing is required to ensure that Ca^{2+} release occurs during the systolic phase of the cardiac cycle and functional silence during diastole.

Luminal Ca^{2+} -dependent deactivation of RyR2 is a process by which the decline in sarcoplasmic reticulum Ca^{2+} that follows sarcoplasmic reticulum Ca^{2+} release renders RyR2s functionally inactive. This results in termination of CICR and induction of a refractory state that suppresses Ca^{2+} release during the diastole, which is an important determinant of the mechanical refractoriness required for efficient relaxation and refilling of the heart.

Regulation

Many proteins interact directly and indirectly with the N-terminal cytoplasmic domain of RyR2, including FK506-binding protein (calstabin2 or FKBP12.6), PKA, Ca^{2+} -calmodulin-dependent kinase II (CaMKII), phosphodiesterase 4D3, calmodulin, protein phosphatases 1 and 2A, and sorcin. CASQ2, junctin, and triadin bind with the luminal (sarcoplasmic reticulum) C-terminus of RyR2.

Calsequestrin

CASQ2 is a low-affinity, high-capacity Ca^{2+} -binding protein, which serves as a Ca^{2+} storage reservoir that is able to bind luminal Ca^{2+} (40 to 50 Ca^{2+} ions per molecule) during diastole, thus buffering Ca^{2+} within the sarcoplasmic reticulum (i.e., preventing Ca^{2+} precipitation and lowering luminal free Ca^{2+} concentration) and preventing diastolic Ca^{2+} release via RyR2 to cytosol. CASQ2 presumably serves as a luminal Ca^{2+} sensor that modulates the responsiveness of the RyR2 to luminal Ca^{2+} . At low luminal Ca^{2+} concentrations, CASQ2 interacts with RyR2 via binding to triadin and junctin and inhibits the activity of the RyR2. When sarcoplasmic reticulum Ca^{2+} levels increase, Ca^{2+} binds to CASQ2, resulting in weakened interactions or complete dissociation of CASQ2 from triadin. This process relieves the inhibitory action of CASQ2 on the RyR2 complex, allows Ca^{2+} release to the cytosol, and hence normalizes sarcoplasmic reticulum Ca^{2+} load. Triadin and junctin not only mediate functional interactions of CASQ2 and RyR2 but also modulate RyR2 function by themselves by increasing the activity of the RyR2 channel. This Ca^{2+} -dependent modulation of RyR2s by triadin, junctin, and CASQ2 may contribute to deactivation and refractoriness of RyR2 channels after sarcoplasmic reticulum Ca^{2+} release.

FK506-Binding Protein

FKBP12.6 (the 12.6-kDa cytosolic FK506-binding protein), also known as calstabin2 (Ca^{2+} channel-stabilizing binding protein), stabilizes the closed conformational state of the RyR2 channel, thus enabling the channel to close completely during diastole (at low intracellular Ca^{2+} concentrations), preventing aberrant Ca^{2+} leakage from the sarcoplasmic reticulum, and ensuring muscle relaxation. PKA phosphorylation of RyR2 decreases the binding affinity of FKBP12.6 to RyR2 and thereby increases the probability of an open state and amplifies the response to Ca^{2+} -dependent activation.

Calmodulin

Calmodulin is a Ca^{2+} -binding protein with ubiquitous expression that has a regulatory function for numerous Ca^{2+} -dependent processes. The main binding partner of calmodulin in cardiac cells is RyR2. Calmodulin has four Ca^{2+} -binding sites and four sites that bind to RyR2 monomers. Calmodulin preferentially inhibits RyR2 at Ca^{2+} concentrations lower than 10 μM by binding to a region on RyR2. Calmodulin may function to assist closing RyR2 following sarcoplasmic reticulum Ca^{2+} release in excitation-contraction coupling.

Protein Kinase A

Stimulation of β -adrenergic receptors results in an increase in cAMP and consequent PKA activation. PKA interacts with the RyR2 channel via binding to the muscle A kinase anchoring protein (mAAP). PKA phosphorylation of RyR2 activates the channel, at least in part by increasing the sensitivity of RyR2 to cytosolic Ca^{2+} and a transient decrease in the binding affinity of calstabin2. This allows for increased sarcoplasmic reticulum Ca^{2+} release on Ca^{2+} influx via I_{CaL} as a part of the fight-or-flight mechanism. By contrast, chronic PKA hyperphosphorylation of RyR2 can result in incomplete channel closure and Ca^{2+} leak during diastole, which causes depletion of the sarcoplasmic reticulum Ca^{2+} store and reduced Ca^{2+} release on receptor activation.

Calcium-Calmodulin-Dependent Protein Kinase II

CaMKII is a dodecameric holoenzyme activated by Ca^{2+} -bound calmodulin, possibly at high cellular Ca^{2+} loads. CaMKII phosphorylation increases RyR2 channel open probability, but to a smaller extent than PKA phosphorylation. CaMKII activity increases at faster heart rates (typically mediated by β -adrenergic stimulation and PKA activation and associated with increased cytosolic Ca^{2+}) and phosphorylates RyR2 to enhance sarcoplasmic reticulum Ca^{2+} release, which helps maintain the positive force-frequency relationship (i.e., cardiac contractility increases as a function of heart rate). Increased CaMKII activity also phosphorylates phospholamban to help accelerate diastolic filling of the ventricles at higher heart rates. Physiologically, sympathetic activation stimulates both PKA and CaMKII, which thus function synergistically. CaMKII is typically considered to be downstream of PKA and elevated Ca^{2+} transients.

Pharmacology

RyR2s are targets of multiple experimental drugs. However, thus far, no compounds in clinical use are known to target RyR2 directly.

The plant alkaloid ryanodine binds the RyR2 channel with high affinity in a Ca^{2+} -dependent and use-dependent fashion, thus making it an important tool for biochemical characterization of the channel. Two ryanodine-binding sites, a high-affinity site and a low-affinity one, have been described at the C-terminus of RyR2. At the high-affinity site, ryanodine induces long-lasting channel openings at a subconductance state, whereas high concentrations block the channel.

Caffeine, in high concentrations (5 to 20 mM), increases the RyR2 sensitivity to Ca^{2+} and ATP and results in increased RyR2 mean open time and open probability. Caffeine is used experimentally to measure sarcoplasmic reticulum Ca^{2+} content indirectly, because its application causes emptying of the sarcoplasmic reticulum Ca^{2+} store.

JTV-519, also known as K201, is a benzothiazepine derivative (an analogue of diltiazem) and an L-type Ca^{2+} channel blocker and stabilizer. JTV-519 can increase the binding affinity of calstabin2 for RyR2, thus stabilizing the closed conformational state of the RyR2 channel and hence preventing diastolic sarcoplasmic reticulum Ca^{2+} leak. JTV-519 can potentially offer an antiarrhythmic benefit in a variety of pathological conditions that lead to destabilization of the RyR2 channel's closed

state, such as RyR2 mutations, hyperphosphorylation of the RyR2 during heart failure, and sarcoplasmic reticulum Ca^{2+} overload.

Among class I antiarrhythmic drugs, only flecainide and propafenone were found to inhibit RyR2 channels (by inducing brief closures of open RyR2 to subconductance states), suppress arrhythmogenic Ca^{2+} sparks, and prevent CPVT in experimental studies. The potency of RyR2 channel inhibition rather than Na^+ channel blockade appears to determine the efficacy of class I agents for the prevention of CPVT. Flecainide has been demonstrated to prevent lethal ventricular arrhythmias in patients with familial CPVT.

Several toxins (e.g., the scorpion toxins imperatoxin A and imperatoxin I), some anticancer drugs (e.g., doxorubicin), and some immunosuppressants (e.g., rapamycin) can potentially cause cardiac adverse events likely related to effects on the gating kinetics of RyR2 channels.

Inherited Channelopathies

Mutations in genes that encode for four key Ca^{2+} regulatory proteins other than L-type Ca^{2+} channels have been implicated in the pathogenesis of CPVT, idiopathic VF, and LQTS (see Table 2.4).

Mutations Related to Ryanodine Receptor

CPVT1, an autosomal-dominant trait, is the most common genetic variant (50% to 70%) of familial CPVT and is caused by mutations in the *RyR2* gene. CPVT mutant RyR2s typically shows gain-of-function defects following channel activation by PKA phosphorylation (in response to β -adrenergic stimulation or caffeine), resulting in uncontrolled Ca^{2+} release from the sarcoplasmic reticulum during electrical diastole, which facilitates the development of DADs and triggered arrhythmias.⁵¹

Missense mutations in *RyR2* also have been linked to a form of arrhythmogenic cardiomyopathy (ARVC-2) characterized by exercise-induced polymorphic VT that does not appear to have a reentrant mechanism, occurring in the absence of significant structural abnormalities. These patients do not develop characteristic features of ARVC on the 12-lead ECG or signal-averaged ECG, and global RV function remains unaffected. ARVC-2 shows a closer resemblance to familial CPVT in both etiology and phenotype; its inclusion under the umbrella term of ARVC remains controversial.

Recently, two different heterozygous mutations in the *RYR2* gene have been identified in a family with multiple idiopathic VF victims. Those mutations resulted in a phenotype distinct from classic RYR2-related CPVT.^{52,53}

Mutations Related to Calsequestrin

CPVT2, an autosomal-recessive disease, is associated with homozygous mutations in the *CASQ2* gene. Heterozygous carriers of one *CASQ2* mutation are usually healthy. While some *CASQ2* mutations are thought to compromise *CASQ2* synthesis and result in reduced expression or complete absence of *CASQ2* in the heart, other mutations seem to cause expression of defective *CASQ2* proteins with abnormal regulation of cellular Ca^{2+} homeostasis. *CASQ2* mutations result in disruption of the control of RyR2s by luminal Ca^{2+} required for effective termination of sarcoplasmic reticulum Ca^{2+} release and prevention of spontaneous Ca^{2+} release during diastole, leading to diminished Ca^{2+} signaling refractoriness and generation of arrhythmogenic spontaneous Ca^{2+} releases.⁵¹

Mutations Related to Calmodulin (Calmodulinopathy)

Three different genes (*CALM1*–*3*) in the human genome encode the exact same calmodulin protein. Recent genetic studies have identified several calmodulin mutations associated with CPVT, LQTS, and idiopathic VF. Defective calmodulin–RyR2 binding results in impaired calmodulin inhibition of RyR2 function with consequent dysregulation of sarcoplasmic reticulum Ca^{2+} release.

CPVT4, an autosomal-dominant trait, is caused by a mutation of *CALM1*. In addition, a familial form of idiopathic VF was linked to mutations of the *CALM1* gene, with autosomal-dominant transmission. Further, de novo mutations in *CALM1*, *CALM2*, or *CALM3* genes were found to disrupt Ca^{2+} -dependent inactivation of the cardiac L-type Ca^{2+} channel ($\text{Ca}_v1.2$), which leads in augmentation of I_{CaL} , prolongation of the plateau phase of action potential, and LQTS phenotype (LQT14–16).^{54,55}

Mutations Related to Triadin

CPVT5, an autosomal-recessive disease, is caused by mutations of the *TRDN* gene (encoding triadin). In addition, homozygous or compound heterozygous loss-of-function mutations in *TRDN* likely reduce triadin-mediated negative feedback on the L-type Ca^{2+} channel, resulting in augmentation of I_{CaL} , prolonged action potential duration, and the recessively inherited LQTS phenotype (LQT17). Intracellular Ca^{2+} overload and increases in spontaneous sarcoplasmic reticulum Ca^{2+} release, particularly in the setting of β -adrenergic stimulation, result in ventricular arrhythmias. LQT17 is characterized by extensive T-wave inversions in the precordial leads V1 through V4, with either persistent or transient QT prolongation, exercise-induced cardiac arrest in early childhood (2 to 6 years of age), and mild-to-moderate proximal skeletal muscle weakness. Because all *TRDN*-null patients display a strikingly similar phenotype, it has been proposed that either triadin knockout syndrome or *TRDN*-mediated autosomal-recessive LQTS should be used rather than LQT17.^{38,56}

Acquired Diseases

RyR2 dysfunction is a key factor leading to arrhythmias in heart failure. Chronic β -adrenergic stimulation results in PKA hyperphosphorylation of RyR2. This process causes the dissociation of the channel-stabilizing protein calstabin and leads to diastolic Ca^{2+} leak from the sarcoplasmic reticulum and the generation of spontaneous Ca^{2+} waves, which can be maintained despite a reduced Ca^{2+} gradient, thus underlying DAD-induced triggered arrhythmias in heart failure.

Importantly, in the setting of digitalis poisoning, the abnormal RyR2 behavior leading to spontaneous Ca^{2+} release and DADs is secondary to the elevation of the sarcoplasmic reticulum Ca^{2+} content (SOICR). In CPVT, on the other hand, spontaneous Ca^{2+} release and DADs can occur without Ca^{2+} overload. Mutations in *RyR2* or *CASQ2* lead to defective Ca^{2+} signaling lowering of the sarcoplasmic reticulum Ca^{2+} threshold for spontaneous Ca^{2+} release below the normal baseline level (“perceived” Ca^{2+} overload). A similar mechanism may underlie triggered arrhythmias in other disease conditions, including heart failure and ischemic heart disease, in which sarcoplasmic reticulum Ca^{2+} release regulation is compromised because of acquired defects in components of the RyR2 channel complex.

CARDIAC GAP JUNCTIONS

Structure and Physiology

Cardiomyocytes make contact with each other via multiple intercalated discs, which mediate the transmission of force, electrical continuity, and chemical communication between adjacent cells. Three types of specialized junctions exist in the intercalated disc: (1) fascia adherens, (2) macula adherens (desmosome), and (3) gap junction (nexus). The fascia adherens is an anchoring site for myofibrils, facilitating the transmission of mechanical energy between neighboring cells. The desmosomes link to the cytoskeleton of adjacent cells to provide strong localized adhesion sites that resist shearing forces generated during contraction. Gap junctions are assemblies of intercellular channels that provide electrical continuity and chemical communication between adjacent cells.⁵⁷

In addition to the end-to-end and side-to-side gap junctions localized at the intercalated discs, lateral (side-to-side) gap junctions can exist in nondisc lateral membranes of cardiomyocytes, but they are much less common, occurring more in atrial than ventricular myocardium.⁵⁸

Each gap junction channel is constructed of two hemichannels (connexons) aligned head-to-head in mirror symmetry across a narrow extracellular gap, one provided by each of the adjoining cells. Each connexon is composed of six integral membrane proteins called connexins (Cx) hexagonally arranged around the pore. Each connexin consists of four membrane-spanning domains (M1 to M4), two extracellular loops (E1, E2), one intracellular loop, and cytoplasmic N- and C-termini. The extracellular loops mediate the docking of the two hemichannels.^{59,60}

Up to 24 different connexin types have been identified. They are named after their theoretical molecular weight in daltons. Three different connexins are prominently expressed in the atrial and ventricular myocardium: Cx40, Cx43, and Cx45. A fourth connexin has been described in the AVN (Cx31.9). Cx40 gap junction channels exhibit the largest conductance and Cx45 the smallest. Although each connexin exhibits a distinct tissue distribution, most cardiomyocytes express more than one connexin isoform. Cx43 is by far the most abundant and is expressed in atrial and ventricular myocytes and distal parts of the Purkinje system. Cx40 is mainly expressed in the atrial myocytes, AVN, and HPS. Cx45 appears to be primarily expressed in nodal tissue (the sinus and compact AVNs), and more weakly in the atrium, HB, bundle branches, and Purkinje fibers.⁶⁰⁻⁶²

Connexons can be composed by the oligomerization of a single connexin type (homomeric) or of different types (heteromeric). In addition, the gap junction channel as a whole may be formed of two matching hemichannels (homotypic) or nonmatching hemichannels (heterotypic; Fig. 2.11).

The different cardiac connexins exhibit distinctive biophysical properties; hence, the connexin composition of a gap junction channel determines its unitary conductance, voltage sensitivity, and ion selectivity. Cx40 gap junctions express the largest conductance, and Cx45 expresses

the smallest. Both Cx40 and Cx45 are highly cation selective, and their conductance is voltage dependent. Cx43 has an intermediate conductance and is nonselective.⁶³

The individual gap junction channels allow exchange of nutrients, metabolites, ions (e.g., Na^+ , Cl^- , K^+ , Ca^{2+}) and small molecules (e.g., cAMP, cGMP, inositol triphosphate [IP3]) with molecular weights up to approximately 1000 Da.

Function

Gap junctions maintain direct cell-to-cell communication in the heart by providing biochemical and low-resistance electrical coupling between adjacent cardiomyocytes. Thus gap junctions are responsible for propagation of the electrical current from one cardiac cell to another and are crucial in myocardial synchronization and heart function. Gap junctions also provide biochemical coupling, which allows intercellular movement of second-messenger substances (e.g., ATP, cyclic nucleotides, and IP3) and hence enables coordinated responses of the myocardial syncytium to physiological stimuli.

The role of gap junction channels in action potential propagation and conduction velocity in cardiac tissue depends primarily on static factors of the channels (e.g., the number of channels, channel conductance, and voltage sensitivity) and dynamic factors (e.g., channel gating kinetics), as well as on properties of the propagated action potential, structural aspects of the cell geometry, and tissue architecture. Tissue-specific connexin expression and gap junction spatial distribution, as well as the variation in the structural composition of gap junction channels, allow for a greater versatility of gap junction physiological features and for disparate conduction properties in cardiac tissue. The myocytes of the sinus and AVNs are equipped with small, sparse, dispersed gap junctions containing Cx45, a connexin that forms low conductance channels; this feature underlies the relatively poor intercellular coupling in nodal tissues, a property that is linked to slowing of conduction. In contrast, ventricular muscle expresses predominantly Cx43 and Cx45, which have larger conductance. Atrial muscle and Purkinje fibers express all three cardiac connexins.^{63,64}

Fig. 2.11 Schematic Representation of Connexins and Gap Junction Channels. (A) Connexins have four transmembrane domains, two extracellular loops, a cytoplasmic loop, and cytoplasmic N- and C-termini. (B) Six connexins oligomerize to form hemichannels called “connexons,” which then align in the extracellular space to complete the formation of gap junction channels. Different connexins can selectively interact with each other to form homomeric, heteromeric, and heterotypic channels, which differ in their content and spatial arrangement of connexin subunits. (From Meşe G, Richard G, White TW. Gap junctions: basic structure and function. *J Invest Dermatol.* 2007;127:2516–2524.)

Under physiological conditions, a given cardiomyocyte in the adult working myocardium is electrically coupled to an average of approximately 11 adjacent cells, with gap junctions predominantly localized at the intercalated discs at the ends of the rod-shaped cells. Lateral (side-to-side) gap junctions in nondisc lateral membranes of cardiomyocytes are much less abundant and occur more often in atrial than ventricular tissues. Thus intercellular current flow occurs primarily at the cell termini, although propagation can occur both longitudinally and transversely. This particular subcellular distribution of gap junctions underlies uniform anisotropic impulse propagation throughout the myocardium, whereby conduction in the direction parallel to the long axis of the myocardial fiber bundles is approximately three to five times more rapid than that in the transverse direction. This property is attributable principally to the lower resistivity of myocardium provided by the gap junctions in the longitudinal versus the transverse direction.^{65,66}

Cx43 hemichannels can occur as free, nonjunctional channels in the plasma membrane. These hemichannels are normally closed but may open in response to various pathological (rather than physiological) triggers.

Regulation

Gap junction channels have a voltage-dependent gating mechanism, depending primarily on transjunctional voltage (i.e., the potential difference between the cytoplasm of the two adjacent cells). At rest, when the junctional voltage is zero, the channels usually are open. During the course of a propagated action potential, the channels tend to close in a voltage- and time-dependent manner. Gap junction channel gating can also be altered by specific changes in intracellular ions and by posttranslational modifications ("loop" gating). Cytosolic Na^+ and Ca^{2+} overload, acidosis, and reduced ATP levels decrease gap junction channel function. Unlike the voltage gate, which closes rapidly and incompletely, the chemical gate closes slowly and completely.

Cx43 gap junction proteins have a short life span (half-life in the order of hours). The life cycle of Cx43 involves connexon delivery to the cell plasma membrane (forward/anterograde trafficking), connexon movement within the plasma membrane (lateral diffusion), and connexon internalization from the plasma membrane (retrograde trafficking). Given the short life span, regulation of gap junction trafficking, assembly and disassembly, and degradation is likely to be critical in the control of intercellular communication.

Phosphorylation also appears to play a key role in channel gating that determines channel conductance and has been implicated in the regulation of the connexin "life cycle" at several stages. Gap junction coupling also is regulated by certain endogenous mediators (e.g., acetylcholine, norepinephrine, and angiotensin), likely via phosphorylation-mediated mechanisms. Importantly, channels composed of different connexins possess different properties and are susceptible to different regulation.

Pharmacology

Several agents have been found to decrease gap junction channel coupling, including long-chain alcohols (e.g., heptanol, octanol), fatty acids (myristoleic acid, decanoic acid, palmitoleic acid), general anesthetics (e.g., halothane, isoflurane), carbachol (an acetylcholine analogue), α -adrenergic agonists (phenylephrine), angiotensin, insulin, insulin-like growth factor, and the nonsteroidal agents fenamates (e.g., flufenamic acid, meclofenamic acid). The mechanisms of action of those agents remain largely unknown.

Antimalarial drugs, particularly quinine and quinine derivatives such as mefloquine, can reduce gap junction channel conductance, and their effects seem to be connexin subtype specific. In addition, it has been

suggested that the cardiac glycosides strophanthidin, ouabain, and digitoxin decrease intercellular coupling.

Experimental evidence suggests that optimization of gap junction conductance can potentially confer an antiarrhythmic effect by ensuring more homogeneous propagation of activation wavefronts and minimizing opportunities for reentrant arrhythmias to develop.⁶³

Some compounds, including antiarrhythmic peptides and their derivatives (e.g., AAP10, ZP123, rotigaptide), can upregulate Cx43 via modulation either synthesis or degradation and enhance gap junctional communication and were found to reduce conduction slowing and prevent AF and ischemic reentrant VT in various cell and animal models. These peptides presumably act by modulating Cx43 phosphorylation.⁶⁷

Inherited Channelopathies

Studies have demonstrated an association between changes in the primary sequence of Cx43, or Cx40 and arrhythmias. Rare single nucleotide polymorphism in the atrial-specific Cx40 gene (*GJA5*) has been found to increase the risk of idiopathic AF.⁶³ *GJA5* mutations have also been linked to progressive cardiac conduction disease.⁶⁸

Cx43 gene (*GJA1*) amino acid substitutions have been described in SIDS and familial AF. Of note, *GJA1* mutations also cause the pleiotropic phenotype of oculodentodigital dysplasia, an autosomal dominant syndrome characterized by craniofacial and limb dysmorphisms, as well as neurologic manifestations. Surprisingly, this phenotype does not include cardiac arrhythmias.⁶⁸

Mutations in desmosomal proteins underlying ARVC can also impair expression of interacting proteins at the intercalated disk (e.g., gap junction or Na^+ channel proteins), giving rise to impairment of intercellular conductance and promoting ventricular arrhythmogenesis, even in the absence of fibrofatty tissue replacement. In particular, Cx43 remodeling in the gap junctions, which contributes to delayed conduction and ventricular arrhythmogenesis, is often observed in ARVC patients. Abnormal electrical coupling and ion channel dysfunction, leading to electrical instability, can promote arrhythmias and predispose patients to high risk of SCD, even in the early disease stages, prior to the development of significant ventricular dysplasia and scarring.⁶⁹⁻⁷¹

Acquired Diseases

Given highly dynamic and active turnover of connexons, remodeling of gap junction coupling can occur rapidly after insult. Modification of cell-to-cell coupling occurs in numerous pathophysiological settings (e.g., acute myocardial ischemia, hypertrophic cardiomyopathies, dilated cardiomyopathies, ischemic cardiomyopathies, and clinical congestive heart failure) as a consequence of acute changes in the average conductance of gap junctions secondary to ischemia, hypoxia, acidification, or an increase in intracellular Ca^{2+} , or it can be produced by changes in expression or cellular distribution patterns of gap junctions.⁶⁰

Remodeling includes a decrease in the number of gap junction channels resulting from the interruption of communication between cells by fibrosis and downregulation of Cx43 formation or of trafficking to the intercalated disc. In addition, gap junctions can become more prominent along lateral membranes of myocytes (so-called structural remodeling). The mislocalization of Cx43 during disease reflects impaired forward trafficking to the intercalated discs. Lateralized Cx43 likely represents protein that is not functional junctions. Influences of Cx43 lateralization on impulse propagation have not yet been well defined.⁶³

Changes in function or remodeling of connexins occur in almost all major arrhythmogenic cardiac disorders. Inactivation of gap junctions decreases transverse conduction velocity to a greater degree than longitudinal conduction, thus resulting in exaggeration of anisotropy and providing a substrate for reentrant activity and increased susceptibility to arrhythmias. Importantly, there is a high redundancy in

connexin expression in the heart with regard to conduction of electrical impulse. It has been shown that a 50% reduction in Cx43 does not alter ventricular impulse conduction. Cx43 expression must decrease by 90% to affect conduction, but even then conduction velocity is reduced only by 20%.

AF is associated with abnormal expression and distribution of atrial Cx40, which can potentially lead to inhomogeneous electrical coupling and abnormal impulse formation and conduction, and thereby provide the substrate for atrial arrhythmias.⁶³

- Mechanism of Unidirectional Block in the Reentrant Circuit, 78

The mechanisms responsible for cardiac arrhythmias are generally divided into categories of disorders of impulse formation (automaticity or triggered activity), disorders of impulse conduction (reentry), or combinations of both. Automaticity is the property of cardiac cells to initiate an impulse spontaneously, without need for prior stimulation. Triggered activity is impulse initiation in cardiac fibers caused by depolarizing oscillations in membrane voltage (known as afterdepolarizations) that occur consequent to one or more preceding action potentials. Reentry occurs when a propagating action potential wave fails to extinguish after initial tissue activation; instead, it blocks in circumscribed areas, circulates around the zones of block, and reenters and reactivates the site of original excitation after it recovers excitability. Reentry is the likely mechanism of most recurrent clinical arrhythmias.¹

Diagnosis of the underlying mechanism of an arrhythmia can be of great importance in guiding appropriate treatment strategies. Spontaneous behavior of the arrhythmia, mode of initiation and termination, and response to programmed electrical stimulation are the most commonly used tools to distinguish among the different mechanisms responsible for cardiac arrhythmias. However, our present diagnostic tools do not always permit unequivocal determination of the electrophysiological (EP) mechanisms responsible for many clinical arrhythmias or their ionic bases. In particular, it can be difficult to distinguish among several mechanisms that appear to have a focal origin with centrifugal spread of activation (automaticity, triggered activity, and microreentry). This is further complicated by the fact that some arrhythmias can be started by one mechanism and perpetuated by another.

AUTOMATICITY

Automaticity, or spontaneous impulse initiation, is the ability of cardiac cells to depolarize spontaneously, reach threshold potential, and initiate a propagated action potential, in the absence of external electrical stimulation. Altered automaticity can be caused by enhanced normal automaticity or by abnormal automaticity.

Enhanced normal automaticity refers to the accelerated generation of an action potential by normal pacemaker tissue and is found in the

primary pacemaker of the heart, the sinus node, as well as in certain subsidiary or latent pacemakers that can become the functional pacemaker under certain conditions. Impulse initiation is a normal property of the primary and latent pacemakers.

Abnormal automaticity occurs in cardiac cells only when there are major abnormalities in their transmembrane potentials, in particular in steady-state depolarization of the membrane potential. This property of abnormal automaticity is not confined to any specific latent pacemaker cell type but can occur almost anywhere in the heart.

The discharge rate of normal or abnormal pacemakers can be influenced by drugs, various forms of cardiac disease, reduction in extracellular potassium (K^+), or alterations of autonomic nervous system tone.

Enhanced Normal Automaticity Pacemaker Mechanisms

Normal automaticity involves a spontaneous, slow, progressive decline in the transmembrane potential (i.e., the membrane voltage becomes less negative) during diastole. This process is known as “spontaneous diastolic depolarization” or “phase 4 depolarization.” Once this spontaneous depolarization reaches threshold (approximately -40 mV), a new action potential is generated (Fig. 3.1) (see Chapter 1).

The ionic mechanisms responsible for normal pacemaker activity in the sinus node are still controversial. The fall in membrane potential during phase 4 seems to arise from a changing balance between positive inward currents, which favor depolarization, and positive outward currents, with a net gain in intracellular positive charges during diastole (i.e., a net inward depolarizing current) (Fig. 3.2).¹

I_K -decay theory. The sinus node lacks the inward rectifier K^+ current (I_{K1}), which acts to stabilize the resting membrane potential (E_m) in the normal working atrial and ventricular myocardium. The outward K^+ currents are carried by the delayed rectifier K^+ channels (I_{Kr} and I_{Ks}), which are responsible for repolarization of the sinus node action potential; those currents decay following repolarization and channel inactivation, allowing the membrane potential to drift toward the more positive equilibrium potentials of other ions (Na^+ , Ca^{2+} , and Cl^-). The decay of the delayed K^+ conductance activated during the preceding action

Fig. 3.1 Normal Cardiac Automaticity. Action potentials from typical sinus nodal and His-Purkinje cells are shown with the voltage scale on the vertical axes; dashed lines are threshold potential, and numbers on the figure refer to phases of the action potential. Note the qualitative differences between the two types of cells, as well as different rates of spontaneous depolarization. Ca^{2+} , Calcium; *HPS*, His-Purkinje system; Na^+ , sodium.

potential was initially thought to play a major role in pacemaker activity (the I_K -decay theory). This model of pacemaker depolarization lost interest after the discovery of the pacemaker current (I_f). Nonetheless, I_K -decay is still believed to contribute to diastolic depolarization (especially the earliest part of the pacemaker potential) by allowing other inward currents to depolarize the myocyte during diastole. Other ionic currents gated by membrane depolarization (i.e., L-type [I_{CaL}] and T-type [I_{CaT}] Ca^{2+} currents), nongated and nonspecific background leak currents, and a current generated by the Na^+ - Ca^{2+} exchanger (I_{Na-Ca}), were also proposed to be involved in pacemaking.²

Membrane clock. Evidence suggests that I_f (named the “funny” current because, unlike most voltage-sensitive currents, it is activated by hyperpolarization rather than depolarization) is one of the most important ionic currents involved in the rate regulation of cardiac pacemaker cells, hence its designation as the pacemaker current. I_f is an inward current carried largely by Na^+ and, to a lesser extent, K^+ ions. I_f channels are deactivated during the action potential upstroke and the initial plateau phase of repolarization. However, they begin to activate at the end of the action potential as repolarization brings the membrane potential to levels more negative than -40 to -50 mV, and I_f is fully activated at approximately -100 mV. Once activated, I_f depolarizes the membrane to a level where the Ca^{2+} current activates to initiate the action potential. In its range of activation, which quite properly comprises the voltage range of diastolic depolarization, the current is inward, and its reversal occurs at approximately -10 to -20 mV because of the mixed Na^+ - K^+ permeability of I_f channels. At the end of the repolarization phase of an action potential, because I_f activation occurs in the background of a decaying outward (K^+ time-dependent) current, the current flow quickly shifts from outward to inward, thus giving rise to a sudden reversal of voltage change (from repolarizing to depolarizing) at the maximum diastolic potential. The major role of I_f has been reinforced by the findings that drugs such as ivabradine targeted to block I_f slow heart rate and mutations in the I_f channel are associated with slowed heart rate.³⁻⁵

The “membrane clock” (also referred to as the “voltage clock” or “ion channel clock”) refers to the time- and voltage-dependent mem-

brane ion channels underlying pacemaking activity, including the decay of the outward rectifier K^+ current and the activation of several inward currents (I_f , I_{CaL} , I_{CaT} , and I_{Na}).

Calcium clock. Several studies have recently demonstrated that I_f is not the only current that can initiate the diastolic depolarization process in the sinus node. In addition to voltage and time, the electrogenic and regulatory molecules on the surface membrane of sinus nodal cells are strongly modulated by Ca^{2+} and phosphorylation, a finding suggesting that intracellular Ca^{2+} is an important player in controlling pacemaker cell automaticity. Newer evidence points to a substantial impact of another current on the late diastolic depolarization; that is, the Na^+ - Ca^{2+} exchanger current (I_{Na-Ca}) activated by submembrane spontaneous rhythmic local Ca^{2+} releases from the sarcoplasmic reticulum (a major Ca^{2+} store within sinus node cells) via the ryanodine receptors (RyR2). Activation of the local oscillatory Ca^{2+} releases is independent of membrane depolarization and is driven by a high level of basal state phosphorylation of Ca^{2+} cycling proteins. Critically timed Ca^{2+} releases occur during the later phase of diastolic depolarization and instantaneously trigger Ca^{2+} extrusion from the cytosol by the Na^+ - Ca^{2+} exchanger operating in the forward mode (one Ca^{2+} out for three Na^+ in). This generates a net inward membrane current that causes the late diastolic depolarization to increase exponentially, thus driving the membrane potential to the threshold to activate a sufficient number of voltage-gated L-type Ca^{2+} channels and leading to generation of the rapid upstroke of the next action potential (see Fig. 1.7). Although regulated by membrane potential and submembrane Ca^{2+} , the Na^+ - Ca^{2+} exchanger does not have time-dependent gating, as do ion channels, but generates an inward current almost instantaneously when submembrane Ca^{2+} concentration increases.^{3,5,6}

Such rhythmic, spontaneous intracellular Ca^{2+} cycling has been referred to as an intracellular “calcium clock.” Phosphorylation-dependent gradation of the speed at which calcium clock cycles is the essential regulatory mechanism of normal pacemaker rate and rhythm. The robust regulation of pacemaker function is ensured by tight integration of the calcium clock and the membrane clock to form the overall “pacemaker clock.” The action potential shape and ion fluxes are tuned by

Fig. 3.2 Ionic Currents Involved in Producing the Sinus Node Pacemaker Potential. A typical action potential of spontaneously beating rabbit sinus node is shown on the top (red trace). The different phases are labeled, with phase 4 representing diastolic depolarization, the defining feature of pacemaking cells. The timing and magnitude of the components of the “membrane clock” is shown in the middle (green bracket). There is voltage-dependent decay of the outward rectifier K^+ current I_K , and voltage-dependent activation of inward currents: I_f , I_{CaL} , and I_{CaT} . The timing and magnitude of the components of the “calcium clock” are shown at the bottom (dark blue bracket). Ca^{2+} entry into the cell via I_{CaL} and I_{CaT} results in spontaneous local Ca^{2+} release (LCR) from the sarcoplasmic reticulum (SR) through RyR2 channels. During phase 4, this rise in total intracellular Ca^{2+} activates the Na^+ - Ca^{2+} exchanger (NCX1) which generates the net inward I_{NCX} (or I_{Na-Ca}) current. Toward the end of diastole, activation of L-type Ca^{2+} channels causes Ca^{2+} -induced Ca^{2+} release from the SR via RyR2, resulting in the whole cell Ca^{2+} transient. Cytoplasmic Ca^{2+} is then removed by the SR Ca^{2+} pump sarcoplasmic/endoplasmic reticulum calcium adenosine triphosphatase (SERCA) and by the sarcolemmal Na^+ - Ca^{2+} exchanger. membrane clocks to sustain operation of the calcium clock, which produces timely and powerful ignition of the membrane clocks to effect action potentials.^{3,7,8}

There remains some degree of uncertainty about the relative role of I_f versus that of intracellular Ca^{2+} cycling in controlling the normal pacemaker cell automaticity and their individual (or mutual) relevance in mediating the positive-negative chronotropic effect of neurotransmitters. Furthermore, the interactions between the membrane ion channel clock and the intracellular calcium clock and the cellular mechanisms underlying this internal calcium clock are not completely elucidated.⁵

Automaticity in subsidiary pacemakers appears to arise via a mechanism similar to that occurring in the sinus node.

Hierarchy of Pacemaker Function

Automaticity is not limited to the cells within the sinus node. Under physiological conditions, cells in parts of the atria and within the atrio-ventricular node (AVN) and the His-Purkinje system (HPS) also possess pacemaking capability. However, the occurrence of spontaneous activity in these cells is prevented by the natural hierarchy of pacemaker function that causes these sites to be latent or subsidiary pacemakers. The

spontaneous discharge rate of the sinus node normally exceeds that of all other subsidiary pacemakers (see Fig. 3.1). Therefore the impulse initiated by the sinus node depolarizes subsidiary pacemaker sites and keeps their activity depressed before they can spontaneously reach threshold. However, slowly depolarizing and previously suppressed pacemakers in the atrium, AVN, or ventricle can become active and assume pacemaker control of the cardiac rhythm if the sinus node pacemaker becomes slow or unable to generate an impulse (e.g., secondary to depressed sinus node automaticity) or if impulses generated by the sinus node are unable to activate the subsidiary pacemaker sites (e.g., sinoatrial exit block or atrioventricular [AV] block). The emergence of subsidiary or latent pacemakers under such circumstances is an appropriate fail-safe mechanism, which ensures that ventricular activation is maintained. Because spontaneous diastolic depolarization is a normal property, the automaticity generated by these cells is classified as *normal*.⁴

There is also a natural hierarchy of the intrinsic rates of subsidiary pacemakers that have normal automaticity, with atrial pacemakers having faster intrinsic rates than AV junctional pacemakers, and AV junctional pacemakers having faster rates than ventricular pacemakers.

Subsidiary Pacemakers

Subsidiary atrial pacemakers. Subsidiary pacemakers have been identified in the atrial myocardium, especially in the crista terminalis, at the junction of the inferior right atrium (RA) and inferior vena cava (IVC), near or on the eustachian ridge, near the coronary sinus (CS) os, in the atrial muscle that extends into the tricuspid and mitral valves, and in the muscle sleeves that extend into the cardiac veins (venae cavae and pulmonary veins).⁴

Latent atrial pacemakers can contribute to impulse initiation in the atrium if the discharge rate of the sinus node is reduced temporarily or permanently. In contrast to the normal sinus node, these latent or ectopic pacemakers usually generate a fast action potential (referring to the rate of upstroke of the action potential [dV/dt]) mediated by Na⁺ fluxes. However, when severely damaged, the atrial tissue may not be able to generate a fast action potential (which is energy dependent) but rather generates a slow, Ca²⁺-mediated action potential (which is energy independent). Automaticity of subsidiary atrial pacemakers can also be enhanced by myocardial ischemia, chronic pulmonary disease, or drugs such as digitalis and alcohol, possibly overriding normal sinus activity.

Subsidiary AV junctional pacemakers. Some data suggest that the AVN itself has pacemaker cells, but that concept is controversial. However, it is clear that the AV junction, which is an area that includes atrial tissue, the AVN, and His-Purkinje tissue, does have pacemaker cells and is capable of exhibiting automaticity.

Subsidiary ventricular pacemakers. In the ventricles, latent pacemakers are found in the HPS, where Purkinje fibers have the property of spontaneous diastolic depolarization. Isolated cells of the HPS discharge spontaneously at rates of 15 to 60 beats/min, whereas ventricular myocardial cells do not normally exhibit spontaneous diastolic depolarization or automaticity. The relatively slow spontaneous discharge rate of the HPS pacemakers, which further decreases from the His bundle (HB) to the distal Purkinje branches, ensures that pacemaker activity in the HPS will be suppressed on a beat-to-beat basis by the more rapid discharge rate of the sinus node and atrial and AV junctional pacemakers. However, enhanced Purkinje fiber automaticity can be induced by certain situations, such as myocardial infarction (MI). In this setting, some Purkinje fibers that survive the infarction develop moderately reduced maximum diastolic membrane potentials and therefore accelerated spontaneous discharge rates.

Regulation of Pacemaker Function

The intrinsic rate at which the sinus node pacemaker cells generate impulses is determined by the interplay of three factors: the maximum diastolic potential, the threshold potential at which the action potential is initiated, and the rate (slope) of phase 4 depolarization (eFig. 3.1). A change in any one of these factors will alter the time required for phase 4 depolarization to carry the membrane potential from its maximum diastolic level to threshold and thus alter the rate of impulse initiation.

The sinus node is innervated by the parasympathetic and sympathetic nervous systems, and the balance between these systems importantly controls the pacemaker rate. The classic concept has been that of a reciprocal relationship between sympathetic and parasympathetic inputs. However, more recent investigations stress dynamic, demand-oriented interactions, and the anatomical distribution of fibers that allows both autonomic systems to act quite selectively. Muscarinic cholinergic and beta₁-adrenergic receptors are nonuniformly distributed in the sinus node, and they modulate both the rate of depolarization and impulse propagation.

Parasympathetic activity. Parasympathetic tone reduces the spontaneous discharge rate of the sinus node, whereas its withdrawal accelerates sinus node automaticity. Acetylcholine, the principal neurotransmitter of the parasympathetic nervous system, inhibits spontaneous impulse generation in the sinus node by increasing K⁺ conductance. Acetylcholine acts through M₂ muscarinic receptors to activate the G_i protein, which subsequently results in activation of I_{KACH} (an acetylcholine-activated subtype of inward rectifying current) in tissues of the sinus node and AVN, as well as of the atria, Purkinje fibers, and ventricles. The increased outward repolarizing K⁺ current leads to membrane hyperpolarization (i.e., the resting potential and the maximum diastolic potential become more negative). The resulting hyperpolarization of the membrane potential lengthens the time required for the membrane potential to depolarize to threshold and thereby decreases the automaticity of the sinus node (see eFig. 3.1). In addition, activation of the G_i protein results in inhibition of beta receptor-stimulated adenylate cyclase activity, thus reducing cyclic adenosine monophosphate (cAMP) and inhibiting protein kinase A, with subsequent inhibition of the inward L-type Ca²⁺ current (I_{CaL}). This results in reduction of the rate of diastolic depolarization because of less Ca²⁺ entry and subsequent slowing of the pacemaker activity. Inhibition of beta receptor-stimulated adenylate cyclase activity can also inhibit the inward I_f current.³

Sympathetic activity. Increased sympathetic nerve traffic and the adrenomedullary release of catecholamines increase sinus node discharge rate. Stimulation of beta₁ receptors by catecholamines enhances I_{CaL} by increasing cAMP and activating the protein kinase A system. The increment in I_{CaL} increases the slope of diastolic depolarization and enhances pacemaker activity (see eFig. 3.1). The redistribution of Ca²⁺ can also increase the completeness and the rate of deactivation of the rapid (I_{Kr}) and slow (I_{Ks}) components of the delayed rectifier K⁺ current. The ensuing decline in the opposing outward current results in a further net increase in inward current. Catecholamines can also enhance the inward I_f current by shifting the voltage dependence of I_f to more positive potentials, thus augmenting the slope of phase 4 and increasing the rate of sinus node firing.³

In addition to altering ionic conductance, changes in autonomic tone can produce changes in the rate of the sinus node by shifting the primary pacemaker region within the pacemaker complex. Mapping of activation indicates that, at faster rates, the sinus node impulse usually originates in the superior portion of the sinus node, whereas at slower rates, it usually arises from a more inferior portion of the sinus node. The sinus node can be insulated from the surrounding atrial myocytes, except at a limited number of preferential exit sites. Shifting pacemaker

eFig. 3.1 Abnormalities of Automaticity. (A) Normal His-Purkinje action potential. (B) Modulation of rate of depolarization from baseline (1) by slowing rate of phase 4 depolarization (2), increasing threshold potential (3), starting from a more negative resting membrane potential (4), all of which slow discharge rate, or by increasing rate of phase 4 depolarization (5), thus yielding a faster discharge rate. (C) Abnormal automaticity with change in action potential contour (resembling sinus nodal cell) when resting membrane potential is less negative, inactivating most sodium channels.

sites can select different exit pathways to the atria. As a result, autonomically mediated shifts of pacemaker regions can be accompanied by changes in the sinus rate. Vagal fibers are denser in the cranial portion of the sinus node, and stimulation of the parasympathetic nervous system shifts the pacemaker center to a more caudal region of the sinus node complex, thus resulting in slowing of the heart rate. In contrast, stimulation of the sympathetic nervous system or withdrawal of vagal stimulation shifts the pacemaker center cranially, resulting in an increase in heart rate.

Atrial, AV junctional, and HPS subsidiary pacemakers are also under similar autonomic control, with the sympathetic nervous system enhancing pacemaker activity through β_1 -adrenergic stimulation and the parasympathetic nervous system inhibiting pacemaker activity through muscarinic receptor stimulation.

Other influences. Adenosine binds to A1-receptors, thus activating $I_{K_{ACH}}$ and increasing outward I_K in a manner similar to that of marked parasympathetic stimulation. It also has similar effects on I_f channels.

Digitalis exerts two effects on the sinus rate. It has a direct positive chronotropic effect on the sinus node, resulting from depolarization of the membrane potential caused by inhibition of the Na^+ - K^+ exchange pump. The reduction in the maximum diastolic membrane potential shortens the time required for the membrane to depolarize to threshold and thereby accelerates the spontaneous discharge rate. However, digitalis also enhances vagal tone, which decreases spontaneous sinus discharge.

Enhanced subsidiary pacemaker activity may not require sympathetic stimulation. Normal automaticity can be affected by certain other factors associated with heart disease. Inhibition of the electrogenic Na^+ - K^+ exchange pump results in a net increase in inward current during diastole because of the decrease in outward current normally generated by the pump, and therefore it can increase automaticity in subsidiary pacemakers sufficiently to cause arrhythmias. This can occur when adenosine triphosphate (ATP) is depleted during prolonged hypoxia or ischemia or in the presence of toxic amounts of digitalis. Hypokalemia can reduce the activity of the Na^+ - K^+ exchange pump, thereby reducing the background repolarizing current and enhancing phase 4 diastolic depolarization. The end result would be an increase in the discharge rate of pacemaking cells. In addition, the flow of current between partially depolarized myocardium and normally polarized latent pacemaker cells can enhance automaticity. This mechanism has been proposed to be a cause of some of the ectopic complexes that arise at the borders of ischemic areas in the ventricle. Slightly increased extracellular K^+ can reduce the maximum diastolic potential (i.e., becomes less negative), thereby also increasing the discharge rate of pacemaking cells. However, a greater increase in extracellular K^+ renders the heart inexcitable by depolarizing the membrane potential and inactivating the Na^+ current (I_{Na}).

Evidence indicates that active and passive changes in the mechanical environment of the heart provide feedback to modify cardiac rate and rhythm and are capable of influencing both the initiation and spread of cardiac excitation. This direction of the crosstalk between cardiac electrical and mechanical activity is referred to as mechanoelectric feedback and is thought to be involved in the adjustment of heart rate to changes in mechanical load, which would help to explain the precise beat-to-beat regulation of cardiac performance. Acute mechanical stretch enhances automaticity, reversibly depolarizes the cell membrane, and shortens the action potential duration. Feedback from cardiac mechanics to electrical activity involves mechanosensitive ion channels and ATP-sensitive K^+ channels. In addition, Na^+ and Ca^{2+} entering the cells via nonselective ion channels are thought to contribute to the genesis of stretch-induced arrhythmia.

Abnormal Automaticity

In the normal heart, automaticity is confined to the sinus node and other specialized conducting tissues. Working atrial and ventricular myocardial cells do not normally exhibit spontaneous diastolic depolarization and do not initiate spontaneous impulses, even when they are not excited for long periods of time by propagating impulses. Although these cells do have an I_f , the range of activation of this current in these cells is much more negative (-120 to -170 mV) than in Purkinje fibers or in the sinus node. As a result, during physiological E_m (-85 to -95 mV), the I_f is not activated and ventricular cells do not depolarize spontaneously. However, when the resting potentials of these cells are depolarized sufficiently, to approximately -70 to -30 mV, spontaneous diastolic depolarization can occur and cause repetitive impulse initiation, a phenomenon called depolarization-induced automaticity or abnormal automaticity (see eFig. 3.1). Similarly, cells in the Purkinje system, which are normally automatic at high levels of membrane potential, show abnormal automaticity when the membrane potential is reduced to approximately -60 mV or less, as can occur in ischemic regions of the heart. When the steady-state membrane potential of Purkinje fibers is reduced to levels more positive to -60 mV, the I_f channels that participate in normal pacemaker activity in Purkinje fibers are closed and nonfunctional, and automaticity is therefore not caused by the normal pacemaker mechanism. However, it can be caused by an “abnormal” mechanism. In contrast, enhanced automaticity of the sinus node, subsidiary atrial pacemakers, or the AVN caused by a mechanism other than acceleration of normal automaticity has not been demonstrated clinically.^{1,9}

A low level of membrane potential is not the only criterion for defining abnormal automaticity. If this were so, the automaticity of the sinus node would have to be considered abnormal. Therefore an important distinction between abnormal and normal automaticity is that the membrane potentials of fibers showing the abnormal type of activity are reduced from their own normal level. For this reason, automaticity in the AVN (e.g., where the membrane potential is normally low) is not classified as abnormal automaticity.

Several different mechanisms probably cause abnormal pacemaker activity at low membrane potentials, including activation and deactivation of the delayed rectifier I_K , intracellular Ca^{2+} release from the sarcoplasmic reticulum that causes activation of inward Ca^{2+} current as well as I_{Na} (through the Na^+ - Ca^{2+} exchanger), and a potential contribution by I_f . It has not been determined which of these mechanisms are operative in the different pathological conditions in which abnormal automaticity can occur.

The upstroke of the spontaneously occurring action potentials generated by abnormal automaticity can be caused by Na^+ or Ca^{2+} inward currents or possibly a combination of the two. In the range of diastolic potentials between approximately -70 and -50 mV, repetitive activity is dependent on extracellular Na^+ concentration and can be decreased or abolished by Na^+ channel blockers. In a diastolic potential range of approximately -50 to -30 mV, Na^+ channels are predominantly inactivated; repetitive activity depends on extracellular Ca^{2+} concentration and is reduced by L-type Ca^{2+} channel blockers.

The intrinsic rate of a focus with abnormal automaticity is a function of the membrane potential. The more positive the membrane potential, the faster the automatic rate (see eFig. 3.1). Abnormal automaticity is less vulnerable to suppression by overdrive pacing (see later). Therefore even occasional slowing of the sinus node rate can allow an ectopic focus with abnormal automaticity to fire without a preceding long period of quiescence. Catecholamines can increase the rate of discharge caused by abnormal automaticity and therefore can contribute to a shift in the pacemaker site from the sinus node to a region with abnormal automaticity.

The decrease in the membrane potential of cardiac cells required for abnormal automaticity to occur can be induced by a variety of factors related to cardiac disease, such as ischemia and infarction. However, the circumstance under which membrane depolarization occurs can influence the development of abnormal automaticity. For example, an increase in extracellular K^+ concentration, as occurs in acutely ischemic myocardium, can reduce membrane potential; however, normal or abnormal automaticity in working atrial, ventricular, and Purkinje fibers usually does not occur because of an increase in K^+ conductance (and hence net outward current) that results from the increase in extracellular K^+ concentration.

Overdrive Suppression of Automatic Rhythms

The sinus node maintains its dominance over subsidiary pacemakers in the AVN and the Purkinje fibers likely by several mechanisms. During sinus rhythm in a normal heart, the intrinsic automatic rate of the sinus node is faster than that of the other potentially automatic cells. Consequently, the latent pacemakers are excited by propagated impulses from the sinus node before they have a chance to depolarize spontaneously to threshold potential. The higher frequency of sinus node discharge also suppresses the automaticity of other pacemaker sites by a mechanism called overdrive suppression. The diastolic (phase 4) depolarization of the latent pacemaker cells with the property of normal automaticity is actually inhibited because the cells are repeatedly depolarized by the impulses from the sinus node. Electrotonic interaction between the pacemaker cells and the nonpacemaker cells in the surrounding myocardium via intercalated discs and gap junctions can also hyperpolarize the latent pacemakers and contribute to their suppression (Fig. 3.3).

The mechanism of overdrive suppression is mediated mostly by enhanced activity of the Na^+-K^+ exchange pump that results from driving a pacemaker cell faster than its intrinsic spontaneous rate. During normal sinus rhythm (NSR), latent pacemakers are depolarized at a higher frequency than their intrinsic rate of automaticity. The increased frequency of depolarizations leads to an increase in intracellular Na^+ , which enters the cell with every action potential. The increased intracellular Na^+ stimulates the Na^+-K^+ exchange pump. Because the Na^+-K^+ exchange pump is electrogenic (i.e., moves more Na^+ outward than K^+ inward), it generates a net outward (hyperpolarizing) current across the cell membrane. This drives the membrane potential more negative, thereby offsetting the depolarizing I_f being carried into the cell and slowing the rate of phase 4 diastolic depolarization. This effectively prevents the I_f from depolarizing the cell to its threshold potential and thereby suppresses spontaneous impulse initiation in these cells.

When the dominant (overdrive) pacemaker is stopped, suppression of subsidiary pacemakers continues because the Na^+-K^+ exchange pump continues to generate the outward current as it reduces the intracellular Na^+ levels toward normal. This continued Na^+-K^+ exchange pump-generated outward current is responsible for the period of quiescence,

which lasts until the intracellular Na^+ concentration, and hence the pump current, becomes low enough to allow subsidiary pacemaker cells to depolarize spontaneously to threshold. Intracellular Na^+ concentration decreases during the quiescent period because Na^+ is constantly being pumped out of the cell and little is entering. The spontaneous rate of the suppressed cell remains lower than it would be otherwise until the intracellular Na^+ concentration has a chance to decrease. Intracellular Na^+ concentration and pump current continue to decline even after spontaneous discharge begins because of the slow firing rate, thus causing a gradual increase in the discharge rate of the subsidiary pacemaker. At slower rates and shorter overdrive periods, the Na^+ load is of lesser magnitude, as is the activity of the Na^+-K^+ pump, resulting in a progressively rapid diastolic depolarization and warm-up. The higher the overdrive rate or the longer the duration of overdrive, the greater the enhancement of pump activity will be, so that the period of quiescence after the cessation of overdrive is directly related to the rate and duration of overdrive.

The sinus node itself also is vulnerable to overdrive suppression. However, when overdrive suppression of the normal sinus node occurs, it is generally of lesser magnitude than that of subsidiary pacemakers overdriven at comparable rates. The sinus node action potential upstroke is largely dependent on the slow inward current carried by I_{CaL} , and far less Na^+ enters the fiber during the upstroke than occurs in latent pacemaker cells such as the Purkinje fibers. As a result, the accumulation of intracellular Na^+ and enhancement of Na^+-K^+ exchange pump activity occur to a lesser degree in sinus node cells after a period of overdrive; therefore there is less overdrive suppression caused by enhanced Na^+-K^+ exchange pump current. The relative resistance of the normal sinus node to overdrive suppression is important in enabling it to remain the dominant pacemaker, even when its rhythm is perturbed transiently by external influences such as transient shifts of the pacemaker to an ectopic site. However, the diseased sinus node can be much more easily overdrive suppressed, such as in the so-called tachycardia-bradycardia syndrome.

Abnormally automatic cells and tissues at reduced levels of membrane potential are less sensitive to overdrive suppression than are cells and tissues that are fully polarized, with enhanced normal automaticity. The amount of overdrive suppression of spontaneous diastolic depolarization that causes abnormal automaticity is directly related to the level of membrane potential at which the automatic rhythm occurs. At low levels of membrane potential, Na^+ channels are inactivated, decreasing the fast inward I_{Na} ; therefore there are reductions in the amount of Na^+ entering the cell during overdrive and the degree of stimulation of the Na^+-K^+ exchange pump. The more polarized the membrane is during phase 4, the larger the amount will be of Na^+ entering the cell with each action potential and the more overdrive suppression will occur. As a result of the lack of overdrive suppression of abnormally automatic cells, even transient sinus pauses can permit an ectopic focus

Fig. 3.3 Overdrive Suppression of Automaticity. A spontaneously firing cell is paced more rapidly, resulting in depression of resting membrane potential; after pacing is stopped, spontaneous depolarization takes longer than usual and gradually resumes baseline rate. *Dashed line*, Threshold potential.

with a slower rate than the sinus node to capture the heart for one or more beats. However, even in situations in which the cells can be sufficiently depolarized to inactivate the I_{Na} and limit intracellular Na^+ load, overdrive suppression can still be observed because of increased intracellular Ca^{2+} loading. Such Ca^{2+} loading can activate Ca^{2+} -dependent K^+ conductance (favoring repolarization) and promote Ca^{2+} extrusion through the Na^+ - Ca^{2+} exchanger and Ca^{2+} channel phosphorylation, thus increasing Na^+ load and thus Na^+ - K^+ exchange pump activity. The increase in intracellular Ca^{2+} load can also reduce the depolarizing I_{CaL} by promoting Ca^{2+} -induced inactivation of the Ca^{2+} current.

In addition to overdrive suppression being of paramount importance for maintenance of NSR, the characteristic response of automatic pacemakers to overdrive is often useful to distinguish automaticity from triggered activity and reentry.

Arrhythmias Caused by Automaticity

Inappropriate Sinus Node Discharge

Examples of these arrhythmias include inappropriate sinus bradycardia, sinus arrest, inappropriate sinus tachycardia, and inappropriate respiratory sinus arrhythmia. Such arrhythmias result simply from an alteration in the rate of impulse initiation by the normal sinus node pacemaker, without a shift of impulse origin to a subsidiary pacemaker at an ectopic site, although there can be shifts of the pacemaker site within the sinus node itself during alterations in sinus rate. These arrhythmias are often a result of the actions of the autonomic nervous system on the sinus node.

Escape Ectopic Automatic Rhythms

Impairment of the sinus node can allow a latent pacemaker to initiate impulse formation. This would be expected to happen when the rate at which the sinus node overdrives subsidiary pacemakers falls considerably below the intrinsic rate of the latent pacemakers or when the inhibitory electrotonic influences between nonpacemaker cells and pacemaker cells are interrupted.

The rate at which the sinus node activates subsidiary pacemakers can be decreased in certain situations, including sinus node dysfunction, with depressed sinus automaticity (secondary to increased vagal tone, drugs, or intrinsic sinus node disease), sinoatrial exit block, AV block, and parasystolic focus. The sinus node and AVN are most sensitive to vagal influence, followed by atrial tissue, with the ventricular conducting system being least sensitive. Moderate vagal stimulation allows the pacemaker to shift to another atrial site, but severe vagal stimulation suppresses the sinus node and blocks conduction at the AVN and therefore can allow a ventricular escape pacemaker to become manifest.

Interruption of the inhibitory electrotonic influences between nonpacemaker cells and pacemaker cells allows those latent pacemakers to fire at their intrinsic rate. Uncoupling can be caused by fibrosis or damage (e.g., infarction) of the tissues surrounding the subsidiary pacemaker cells or by reduction in gap junction conductance secondary to increased intracellular Ca^{2+} , which can be caused by digitalis. Some inhibition of the sinus node is still necessary for the site of impulse initiation to shift to an ectopic site that is no longer inhibited by uncoupling from surrounding cells because the intrinsic firing rate of subsidiary pacemakers is still slower than that of the sinus node.

Accelerated Ectopic Automatic Rhythms

Accelerated ectopic automatic rhythms are caused by enhanced normal automaticity of subsidiary pacemakers. The rate of discharge of these latent pacemakers is then faster than the expected intrinsic automatic rate. Once the enhanced rate exceeds that of the sinus node, the enhanced ectopic pacemaker prevails and overdrives the sinus node and other

subsidiary pacemakers. A premature impulse caused by enhanced automaticity of latent pacemakers comes *early* in the normal rhythm. In contrast, an escape beat secondary to relief of overdrive suppression occurs *late* in normal rhythm.

Enhanced automaticity is usually caused by increased sympathetic tone, which steepens the slope of diastolic depolarization of latent pacemaker cells and diminishes the inhibitory effects of overdrive. Such sympathetic effects can be localized to subsidiary pacemakers in the absence of sinus node stimulation. Other causes of enhanced normal automaticity include periods of hypoxemia, ischemia, electrolyte disturbances, and certain drug toxicities. There is evidence that in the subacute phase of myocardial ischemia, increased activity of the sympathetic nervous system can enhance automaticity of Purkinje fibers, thus enabling them to escape from sinus node domination.

Parasystole

Parasystole is a result of interaction between two fixed rate pacemakers having different discharge rates. Parasystolic pacemakers can exist in either the atrium or the ventricle. The latent pacemaker is protected from being overdriven by the dominant rhythm (usually NSR) by intermittent or constant entrance block (i.e., impulses of sinus origin fail to depolarize the latent pacemaker secondary to block in the tissue surrounding the latent pacemaker focus).

Various mechanisms have been postulated to explain the protected zone surrounding the ectopic focus. It is possible that the depolarized level of membrane potential at which abnormal automaticity occurs can cause entrance block, leading to parasystole. This would be an example of an arrhythmia caused by a combination of an abnormality of impulse conduction and impulse initiation. However, such block must be unidirectional, so that activity from the ectopic pacemaker can exit and produce depolarization whenever the surrounding myocardium is excitable. The protected pacemaker is said to be a parasystolic focus. In general, under these conditions, a protected focus of automaticity of this type fires at its own intrinsic frequency, and the intervals between the discharges of each pacemaker are multiples of its intrinsic discharge rate (sometimes described as *fixed parasystole*). Therefore on the surface electrocardiogram (ECG) the coupling intervals of the manifest ectopic beats wander through the basic cycle of the sinus rhythm. Accordingly, the traditional ECG criteria used to recognize the fixed form of parasystole include: (1) the presence of variable coupling intervals of the manifest ectopic beats; (2) interectopic intervals that are simple multiples of a common denominator; and (3) the presence of fusion beats. Occasionally, the parasystolic focus can exhibit exit block, during which it may fail to depolarize excitable myocardium.¹⁰

Although the parasystolic focus is protected, it may not be totally immune to the surrounding electrical activity. The effective electrical communication that permits the emergence of the ectopic discharges can also allow the rhythmic activity of the surrounding tissues to electrotonically influence the periodicity of the pacemaker discharge rate (described as *modulated parasystole*). Electrotonic influences arriving during the early stage of diastolic depolarization result in a delay in the firing of the parasystolic focus, whereas those arriving late accelerate the discharge of the parasystolic focus. As a consequence, the dominant pacemaker can entrain the partially protected parasystolic focus and force it to discharge at periods that may be faster or slower than its own intrinsic cycle and give rise to premature discharges whose patterns depend on the degree of modulation and the basic heart rate, occasionally mimic reentry, and occur at fixed coupling intervals. Therefore appropriate diagnosis of modulated parasystole relies on the construction of a phase response curve as theoretical evidence of modulation of the ectopic pacemaker cycle length (CL) by the electrotonic activity generated by the sinus discharges across the area of protection.

All these features of abnormal automaticity can be found in the Purkinje fibers that survive in regions of transmural MI and cause ventricular arrhythmias during the subacute phase.

Arrhythmias Caused by Abnormal Automaticity

There appears to be an association between abnormal Purkinje fiber automaticity and the arrhythmias that occur during the acute phase of MI (e.g., an accelerated idioventricular rhythm). However, the role of abnormal automaticity in the development of ventricular arrhythmias associated with chronic ischemic heart disease is less certain. In addition, isolated myocytes obtained from hypertrophied and failing hearts have been shown to manifest spontaneous diastolic depolarization and enhanced I_b findings, suggesting that abnormal automaticity can contribute to the occurrence of some arrhythmias in heart failure and ventricular hypertrophy.¹⁰

Abnormal automaticity can underlie atrial tachycardia, accelerated idioventricular rhythms, and ventricular tachycardia (VT), particularly that associated with ischemia and reperfusion. It has also been suggested that injury currents at the borders of ischemic zones can depolarize adjacent nonischemic tissue, thus predisposing to automatic VT.

Although automaticity is not responsible for most clinical tachyarrhythmias, which are usually caused by reentry or triggered activity, normal or abnormal automaticity can lead to arrhythmias caused by nonautomatic mechanisms. Premature beats, caused by automaticity, can initiate reentry. Rapid automatic activity in sites such as the cardiac veins can cause fibrillatory conduction, reentry, and atrial fibrillation (AF).

TRIGGERED ACTIVITY

Triggered activity is impulse initiation in cardiac fibers caused by afterdepolarizations that occur consequent to a preceding impulse or series of impulses. Afterdepolarizations are depolarizing oscillations in membrane potential that follow the upstroke of a preceding action potential. Afterdepolarizations can occur early during the repolarization phase of the action potential (early afterdepolarization [EAD]) or late, after completion of the repolarization phase (delayed afterdepolarization [DAD]) (Fig. 3.4). When either type of afterdepolarization is large enough to reach the threshold potential for activation of a regenerative inward current, a new action potential is generated, which is referred to as *triggered*.¹

Unlike automaticity, triggered activity is not a self-generating rhythm. Instead, triggered activity occurs as a response to a preceding impulse (the trigger). Automatic rhythms, on the other hand, can arise *de novo* in the absence of any prior electrical activity.

Delayed Afterdepolarizations and Triggered Activity

DADs are oscillations in membrane voltage that occur after completion of repolarization of the action potential (i.e., during phase 4). The

Fig. 3.4 Types of Afterdepolarizations. Afterdepolarizations are indicated by arrows. Purkinje cell action potentials are shown with phase 2 early afterdepolarizations (EADs) (A) and phase 3 EADs (B), as well as delayed afterdepolarizations (C), which occur after full repolarization.

transient nature of the DAD distinguishes it from normal spontaneous diastolic (pacemaker) depolarization, during which the membrane potential declines almost monotonically until the next action potential occurs. DADs may or may not reach threshold. Subthreshold DADs do not initiate action potentials or trigger arrhythmias. When a DAD does reach threshold, only one triggered action potential occurs (Fig. 3.5). The triggered action potential can also be followed by a DAD that, again, may or may not reach threshold and may or may not trigger another action potential. The first triggered action potential is often followed by a short or long train of additional triggered action potentials, each arising from the DAD caused by the previous action potential.¹⁰

Ionic Basis of Delayed Afterdepolarizations

DADs usually occur under a variety of conditions in which Ca^{2+} overload develops in the cytoplasm and sarcoplasmic reticulum. During the plateau phase of the normal action potential, Ca^{2+} flows through voltage-dependent L-type Ca^{2+} channels (I_{CaL}). Although the rise in intracellular Ca^{2+} is small and not sufficient to induce contraction, the small amount of Ca^{2+} entering the cell via I_{CaL} triggers a massive release of Ca^{2+} from the sarcoplasmic reticulum (the major store for Ca^{2+}) into the cytosol by opening the RyR2 channels (present in the membrane of the sarcoplasmic reticulum) in a process known as calcium-induced calcium release (CICR). During electrical diastole, most of the surplus Ca^{2+} in the cytosol is resealed into the sarcoplasmic reticulum by the sarcoplasmic/endoplasmic reticulum calcium adenosine triphosphatase (SERCA), the activity of which is controlled by the phosphoprotein phospholamban. In addition, some of the Ca^{2+} is extruded from the cell by the $\text{Na}^+/\text{Ca}^{2+}$ exchanger to balance the Ca^{2+} that enters via I_{CaL} . Recurring Ca^{2+} release-uptake cycles provide the basis for periodic elevations of the cytosolic Ca^{2+} concentration and contractions of myocytes, hence for the orderly beating of the heart (Fig. 3.6).^{10,11}

Under various pathological conditions, Ca^{2+} concentration in the sarcoplasmic reticulum can rise to a critical level during repolarization (i.e., Ca^{2+} overload), at which time a secondary spontaneous release of Ca^{2+} from the sarcoplasmic reticulum occurs after the action potential, rather than as a part of excitation-contraction coupling. This secondary release of Ca^{2+} results in inappropriately timed Ca^{2+} transients and

Fig. 3.5 Behavior of Delayed Afterdepolarizations (DADs). (A) The DAD is seen following the action potential at slow rates. (B) At faster rates, the DAD occurs slightly earlier and increases in amplitude. (C) At still more rapid rates, the DAD occurs even earlier and eventually reaches threshold, resulting in sustained firing.

contractions. Spontaneous Ca^{2+} waves can be arrhythmogenic; they induce Ca^{2+} -dependent depolarizing membrane currents (transient inward current [I_{ti}]), mainly by activation of the Na^+ - Ca^{2+} exchanger. Increases in intracellular Ca^{2+} levels can stimulate the Na^+ - Ca^{2+} exchanger ($I_{\text{Na-Ca}}$), which exchanges three Na^+ ions for one Ca^{2+} ion; the direction depends on the Na^+ and Ca^{2+} concentrations on the two sides of the membrane and the E_m difference. At resting E_m and during a spontaneous sarcoplasmic reticulum Ca^{2+} release event, this exchanger operates in the forward mode (three Na^+ ions in for one Ca^{2+} ion out) and generates a net Na^+ influx, causing transient oscillations of the membrane potential (DADs). After one or several DADs, myoplasmic Ca^{2+} can decrease because the Na^+ - Ca^{2+} exchanger extrudes Ca^{2+} from the cell, and the membrane potential stops oscillating.^{12,13}

When the DADs are of low amplitude (*subthreshold* DAD), they usually are not apparent or clinically significant. However, during pathological conditions (e.g., myocardial ischemia, acidosis, hypomagnesemia, digitalis toxicity, and increased catecholamines), the amplitude of the Ca^{2+} -mediated membrane depolarization is increased and can reach the stimulation threshold (*suprathreshold* DAD) and an action potential is triggered (called *triggered activity*). If this process continues, sustained tachycardia will develop. Triggered action potentials can also initiate reentry when they encounter a vulnerable tissue substrate.

Probably the most important influence that causes subthreshold DADs to reach threshold is a decrease in the initiating CL because that increases both the amplitude and rate of the DADs. Therefore initiation of arrhythmias triggered by DADs can be facilitated by a spontaneous or pacing-induced increase in the heart rate.

Subthreshold DADs can also play a role in arrhythmogenesis by partially depolarizing the cell membrane and hence inactivating a portion of Na^+ channels and reducing their availability during the subsequent (triggered or nontriggered) action potential. The resultant regional dispersion of excitability or refractoriness can generate a tissue substrate vulnerable to unidirectional conduction block and reentry.¹⁴

Role of Delayed Afterdepolarizations in Arrhythmogenesis

A suprathreshold DAD can trigger an action potential and generate triggered activity, which can cause focal, nonreentrant arrhythmias (triggered activity atrial or ventricular ectopic beats or tachycardia) or, when it encounters a vulnerable tissue substrate, the triggered action potential can act as a trigger for initiation of reentrant arrhythmias.¹²

Both suprathreshold and subthreshold DADs can potentially generate a vulnerable substrate and promote reentry by regionally decreasing excitability sufficiently to cause regional conduction block of a subsequent nontriggered action potential. In addition, when both subthreshold and suprathreshold DADs coexist in the same tissue, the combination of triggers and a vulnerable substrate can lead directly to reentry initiation. DADs can potentially generate both a vulnerable substrate that promotes reentry, as well as a trigger for initiation of reentrant arrhythmias. In some regions, suprathreshold DADs can trigger an action potential, whereas in other regions, subthreshold DADs promoting regional conduction block. Once the triggered action potential propagates to the region of conduction block, it may initiate reentry.^{14,15}

DAD-related triggered activity is thought to be a mechanism for tachyarrhythmia associated with MI, reperfusion injury, digitalis toxicity,

and some idiopathic VTs, as well as some arrhythmias associated with inherited channelopathies. DADs are more likely to occur with fast spontaneous or paced rates or with increased premature beats.⁹

Digitalis. Digitalis causes DAD-dependent triggered arrhythmias by inhibiting the $\text{Na}^+\text{-K}^+$ exchange pump. In toxic amounts, this effect results in the accumulation of intracellular Na^+ and consequently an enhancement of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger in the reverse mode (three Na^+ ions out for one Ca^{2+} ion in) and an accumulation of intracellular Ca^{2+} . Spontaneously occurring accelerated ventricular arrhythmias that occur during digitalis toxicity are likely to be caused by DADs. Triggered ventricular arrhythmias caused by digitalis also can be initiated by pacing at rapid rates. As toxicity progresses, the duration of the trains of repetitive responses induced by pacing increases.

Catecholamines. Catecholamines can facilitate the development of DADs by increasing intracellular Ca^{2+} overload via several mechanisms, including (1) increasing the I_{CaL} through stimulation of beta-adrenergic receptors and increasing cAMP, which results in an increase in transsarcolemmal Ca^{2+} influx and intracellular Ca^{2+} overload (see Fig. 3.6); (2) enhancing the activity of the $\text{Na}^+\text{-Ca}^{2+}$ exchanger, thus increasing the likelihood of DAD-mediated triggered activity; (3) enhancing the uptake of Ca^{2+} by the sarcoplasmic reticulum, leading to increased Ca^{2+} stored in the sarcoplasmic reticulum and the subsequent release of an increased amount of Ca^{2+} from the sarcoplasmic reticulum during contraction; and (4) increasing the heart rate.

Sympathetic stimulation can potentially cause triggered atrial and ventricular arrhythmias and possibly underlies some of the ventricular arrhythmias that accompany exercise and those occurring during ischemia and infarction.

Myocardial ischemia. Elevations in intracellular Ca^{2+} in the ischemic myocardium are also associated with DADs and triggered arrhythmias. Accumulation of lysophosphoglycerides in the ischemic myocardium, with consequent Na^+ and Ca^{2+} overload, has been suggested as a mechanism for DADs and triggered activity. Cells from damaged areas or surviving the infarction can display spontaneous release of Ca^{2+} from sarcoplasmic reticulum, which can generate waves of intracellular Ca^{2+} elevation and arrhythmias.

Genetic mutations. DADs can be caused by genetic defects that impair the ability of the sarcoplasmic reticulum to sequester Ca^{2+} during diastole. Mutations in the cardiac RyR2, the sarcoplasmic reticulum Ca^{2+} release channel in the heart, have been identified in kindreds with the syndrome of catecholaminergic polymorphic VT and ventricular fibrillation (VF) with short QT intervals. It seems likely that perturbed intracellular Ca^{2+} and perhaps also DADs underlie arrhythmias in this syndrome (see Fig. 3.6).¹⁶

Drugs. Several drugs can inhibit DAD-related triggered activity via different mechanisms, including reduction of the inward Ca^{2+} current and intracellular Ca^{2+} overload (Ca^{2+} channel blockers, beta-adrenergic blockers), reduction of Ca^{2+} release from the sarcoplasmic reticulum (caffeine, ryanodine, thapsigargin, cyclopiazonic acid), and reduction of the inward I_{Na} (tetrodotoxin, lidocaine, phenytoin).

Properties of Delayed Afterdepolarizations

The amplitude of DADs and the possibility of triggered activity are influenced by the level of membrane potential at which the action potential occurs. The reduction of the membrane potential during DADs may also result in Na^+ channel inactivation and hence slowing of conduction.

The duration of the action potential is a critical determinant of the presence of DADs. Longer action potentials, which are associated with more transsarcolemmal Ca^{2+} influx, are more likely to be associated with DADs. Drugs that prolong action potential duration (e.g., class IA antiarrhythmic agents) can increase DAD amplitude, whereas drugs

that shorten action potential duration (e.g., class IB antiarrhythmic agents) can decrease DAD amplitude.

The number of the action potentials preceding the DAD affects the amplitude of the DAD (i.e., after a period of quiescence, the initiation of a single action potential can be followed by either no DAD or only a small one). With continued stimulation, the DADs increase in amplitude, and triggered activity can eventually occur.

The amplitude of DADs and the coupling interval between the first triggered impulse and the last stimulated impulse that induced them are directly related to the drive CL at which triggered impulses are initiated. A decrease in the basic drive CL (even a single drive cycle; i.e., premature impulse), in addition to increasing the DAD amplitude, results in a decrease in the coupling interval between the last drive cycle and the first DAD-triggered impulse, with respect to the last driven action potential, and an increase of the rate of DADs. Triggered activity tends to be induced by a critical decrease in the drive CL, either spontaneous, such as in sinus tachycardia, or pacing induced. The increased time during which the membrane is in the depolarized state at shorter stimulation CLs or after premature impulses increases Ca^{2+} in the myoplasm and the sarcoplasmic reticulum (because of repeated activation of I_{CaL}), thus increasing the I_{ti} responsible for the increased DAD amplitude, causing the current to reach its maximum amplitude more rapidly, and decreasing the coupling interval of triggered impulses. This characteristic property can help to distinguish triggered activity from reentrant activity because the relationship for reentry impulses initiated by rapid stimulation is often the opposite (i.e., as the drive CL is reduced, the first reentrant impulse occurs later with respect to the last driven action potential because of rate-dependent conduction slowing in the reentrant pathway).

In general, triggered activity is markedly influenced by overdrive pacing. These effects are dependent on both the rate and the duration of overdrive pacing. When overdrive pacing is performed for a critical duration of time and at a critical rate during a catecholamine-dependent triggered rhythm, the rate of triggered activity slows until the triggered rhythm stops, because of enhanced activity of the electrogenic $\text{Na}^+\text{-K}^+$ exchange pump induced by the increase in intracellular Na^+ caused by the increased number of action potentials. When overdrive pacing is not rapid enough to terminate the triggered rhythm, it can cause overdrive *acceleration* (in contrast to overdrive suppression observed with automatic rhythms). Single premature stimuli also can terminate triggered rhythms, although termination is much less common than it is by overdrive pacing.

EADs and triggered activity. EADs are oscillations in membrane potential that occur during the action potential and interrupt the orderly repolarization of the cardiomyocyte. EADs manifest as an abrupt change in the time course of repolarization of an action potential such that the membrane voltage suddenly shifts in a depolarizing direction.^{12,17}

Ionic Basis of Early Afterdepolarizations

Normal cardiac repolarization relies on a critical balance between depolarizing inward currents and repolarizing outward currents during the action potential plateau. Repolarization has built-in redundancy (“repolarization reserve”) to protect against excessive prolongation of the action potential duration. The plateau of the action potential is a time of high membrane resistance (i.e., membrane conductance to all ions falls to rather low values), when there is little current flow. Consequently, small changes in repolarizing or depolarizing currents can have profound effects on the action potential duration and profile. Normally, during phases 2 and 3, the net membrane current is outward. Any factor that transiently shifts the net current in the inward direction can potentially overcome and reverse repolarization (a condition termed “reduced

repolarization reserve”) and lead to EADs and EAD-related arrhythmias. Such a shift can arise from decreased outward (repolarizing) currents (mostly carried by K^+ at that time), increased inward (depolarizing) currents (carried by Na^+ or Ca^{2+} at that time), or both. However, although reduced repolarization reserve is sufficient to prolong action potential duration, it is not sufficient to produce EADs. Other conditions are required to generate the voltage oscillations pathognomonic of EADs, which arise from different causes. The most critical to the dynamics of EAD oscillations include window I_{CaL} , late I_{Na} , and I_{Ks} . In addition, EADs can also be promoted by intracellular Ca^{2+} oscillations or by prolonged Ca^{2+} transients via Na^+-Ca^{2+} exchanger current (I_{Na-Ca}).¹²

EADs have been classified as phase 2 (occurring at the plateau level of membrane potential) and phase 3 (occurring during phase 3 of repolarization) (see Fig. 3.4). The ionic mechanisms of phase 2 and phase 3 EADs and the upstrokes of the action potentials they elicit can

differ. At the depolarized membrane voltages of phase 2, Na^+ channels are inactivated; hence the I_{CaL} and I_{Na-Ca} are the major currents potentially responsible for EADs. Voltage steady-state activation and inactivation of the L-type Ca^{2+} channels are sigmoidal, with an activation range over -40 to $+10$ mV (with a half-activation potential near -15 mV) and a half-inactivation potential near -35 mV. However, a relief of inactivation for voltages positive to 0 mV leads to a U-shaped voltage dependence for steady-state inactivation. Overlap of the steady-state voltage-dependent inactivation and activation relations defines a “window” current near the action potential plateau, within which transitions from closed and open states can occur. As the action potential repolarizes into the window region, I_{CaL} increases and can potentially be sufficient to reverse repolarization, thus generating the EAD upstroke (Fig. 3.7).¹¹

The cardiac Na^+-Ca^{2+} exchanger exchanges three Na^+ ions for one Ca^{2+} ion; the direction is dependent on the Na^+ and Ca^{2+} concentrations

Fig. 3.7 Mechanisms Underlying Early Afterdepolarization (EADs). (A) Normal action potential (left) and an action potential with phase 2 EAD (solid line) or phase 3 EAD (dashed line) (right). (B) Schematic plot of L-type calcium (Ca^{2+}) channel conductance (G_{CaL}) versus membrane voltage (mV) showing the window L-type inward Ca^{2+} current (I_{CaL}) region (purple area) where the steady-state activation (SSA) and steady-state inactivation (SSI) curves overlap and a fraction of Ca^{2+} channels remain continuously open. Dashed lines show a potential therapeutic intervention that shifts the SSA and SSI curves to reduce the overlapping window current region. (C) Schematic diagram illustrating the interaction between time-dependent I_{CaL} reactivation (dashed blue lines) and time-dependent deactivation of repolarizing currents (I_K) (dashed red lines) in the window voltage range during action potential repolarization. For the normal action potential (left), the repolarization rate is too fast for I_{CaL} to grow larger than I_K . However, if the repolarization rate is too slow, I_{CaL} can grow larger than I_K , thereby reversing repolarization to cause an EAD (right). (From Weiss JN, Garfinkel A, Karagueuzian HS, et al. Early afterdepolarizations and cardiac arrhythmias. *Heart Rhythm*. 2010;7:1891–1899.)

on the two sides of the membrane and the transmembrane potential difference. When operating in forward mode, this exchanger generates a net Na^+ influx, thereby resisting repolarization. The increase in the window I_{CaL} results in Ca^{2+} influx into the cell, which further increases $I_{\text{Na-Ca}}$ in the forward mode, thus possibly facilitating EAD formation and increasing the probability of an EAD-triggered action potential.

After opening, most Na^+ channels quickly inactivate to prevent passage of Na^+ and remain inactivated throughout the duration of the plateau phase of the action potential. However, under pathophysiological conditions (e.g., type 3 long-QT syndrome [LQTS], heart failure, cardiomyopathy, ischemia, drugs), Na^+ channel inactivation may be either delayed or reversed to allow channel reopenings before repolarization of the action potential, resulting in a small residual inward current (called “late I_{Na} ,” I_{NaL}) that persists throughout the action potential plateau. The inward late I_{Na} acts to slow repolarization and prolong the action potential duration and hence promotes EADs. Besides late I_{Na} , increased “window I_{Na} ” (due to delayed inactivation or shifts in the voltage dependence of activation/inactivation) may also promote EADs. The role of the late I_{Na} and window I_{Na} in EAD genesis is similar to the window I_{CaL} .^{17,18}

It was traditionally thought that, unlike DADs, EADs do not depend on a rise in intracellular Ca^{2+} ; instead, action potential prolongation and reactivation of depolarizing currents are fundamental to their production. More recent experimental evidence suggested a previously unappreciated interrelationship between intracellular Ca^{2+} loading and EADs. Cytosolic Ca^{2+} levels can increase when action potentials are prolonged. This situation, in turn, appears to enhance I_{CaL} (possibly via Ca^{2+} -calmodulin kinase activation), thus further prolonging the action potential duration as well as providing the inward current driving EADs. Intracellular Ca^{2+} loading by action potential prolongation can also enhance the likelihood of DADs. The interrelationship among intracellular Ca^{2+} , DADs, and EADs can be one explanation for the susceptibility of hearts that are Ca^{2+} loaded (e.g., in ischemia or congestive heart failure) to develop arrhythmias, particularly on exposure to action potential-prolonging drugs.

EADs occurring late in repolarization develop at membrane potentials more negative than -60 mV in atrial, ventricular, or Purkinje cells that have normal resting potentials. Normally, a net outward membrane current shifts the membrane potential progressively in a negative direction during phase 3 repolarization of the action potential. Despite fewer data, it has been suggested that current through the Na^+ - Ca^{2+} exchanger and possibly the I_{Na} can participate in the activation of phase 3 EADs. Nevertheless, this concept was questioned by a study suggesting that phase 2 EADs appear to be responsible for inducing phase 3 EADs through electrotonic interactions and that a large voltage gradient related to heterogeneous repolarization is essential for phase 3 EADs.^{19,20}

The upstrokes of the action potentials elicited by phase 2 and phase 3 EADs also differ. Phase 2 EAD-triggered action potential upstrokes are exclusively mediated by Ca^{2+} currents. Even when these triggered action potentials do not propagate, they can substantially exaggerate heterogeneity of the time course of repolarization of the action potential (a key substrate for reentry) because EADs occur more readily in some regions (e.g., Purkinje fibers, mid left ventricular [LV] myocardium, right ventricular outflow tract [RVOT] epicardium) than others (e.g., LV epicardium, endocardium). Action potentials triggered by phase 3 EADs arise from more negative membrane voltages. Therefore the upstrokes can be caused by Na^+ and Ca^{2+} currents and are more likely to propagate.²¹

Under certain conditions, when an EAD is large enough, the decrease in membrane potential leads to an increase in net inward (depolarizing) current and a second upstroke or an action potential is *triggered* before complete repolarization of the first. The triggered action potential also can be followed by other action potentials, all occurring at the low level

of membrane potential characteristic of the plateau or at the higher level of membrane potential of later phase 3 (eFig. 3.2). The sustained rhythmic activity can continue for a variable number of impulses and terminates when repolarization of the initiating action potential returns membrane potential to a high level. As repolarization occurs, the rate of the triggered rhythm slows because the rate is dependent on the level of membrane potential. Sometimes repolarization to the high level of membrane potential may not occur, and membrane potential can remain at the plateau level or at a level intermediate between the plateau level and the resting potential. The sustained rhythmic activity then can continue at the reduced level of membrane potential and assumes the characteristics of abnormal automaticity. However, in contrast to automatic rhythms, without the initiating action potential, there can be no triggered action potentials.

The ability of the triggered action potentials to propagate is related to the level of membrane potential at which the triggered action potential occurs. The more negative the membrane potential, the more Na^+ channels are available for activation, the greater the influx of Na^+ into the cell during phase 0, and the higher the conduction velocity. At more positive membrane potentials of the plateau (phase 2) and early during phase 3, most Na^+ channels are still inactivated, and the triggered action potentials most likely have upstrokes caused by the inward I_{CaL} . Therefore those triggered action potentials have slow upstrokes and are less able to propagate. Increased dispersion of repolarization facilitates the ability of phase 2 EADs to trigger propagating ventricular responses.

Role of Early Afterdepolarizations in Arrhythmogenesis

Both suprathreshold and subthreshold EADs can create dispersion of refractoriness and a tissue substrate vulnerable to reentry. When EADs reach the threshold to propagate, they generate triggers that initiate reentry in the vulnerable substrate. Therefore, depending on the cellular and tissue properties, EADs can result in purely reentrant arrhythmias, multiple shifting foci, and a mixture of multiple shifting foci and reentry.^{12,22}

A fundamental condition that underlies the development of EADs is action potential prolongation, which is manifest on the surface ECG by QT prolongation. An EAD occurs when the repolarization phase is prolonged either in acquired conditions (e.g., heart failure) and inherited diseases (e.g., LQTS). Other conditions that can contribute to a prolongation of the action potential and lead to EADs include electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia, acidosis), bradycardia, catecholamines, and drugs that block K^+ currents.^{22,23}

Drugs. Drugs are the most common cause of EAD-mediated arrhythmias. Class IA and III antiarrhythmic agents prolong the action potential duration and the QT interval, effects intended to be therapeutic but frequently causing proarrhythmia. Noncardiac drugs such as some phenothiazines, some nonsedating antihistamines, and some antibiotics can also prolong the action potential duration and predispose to EAD-mediated triggered arrhythmias, particularly when there is associated hypokalemia or bradycardia.²⁴ Decreased extracellular K^+ concentration paradoxically decreases some membrane I_{K} (particularly the I_{Kr}) in the ventricular myocyte. This finding explains why hypokalemia causes action potential prolongation and EADs. Of note, EADs are opposed by ATP-dependent K^+ channel (I_{KATP}) openers (pinacidil, cromakalim, rimakalim, and nicorandil), magnesium, alpha-adrenergic blockade, tetrodotoxin, nitrendipine, and antiarrhythmic drugs that shorten action potential (e.g., lidocaine and mexiletine). Alpha-adrenergic stimulation can exacerbate EADs.^{25,26}

Long QT syndromes. EAD-mediated triggered activity likely underlies initiation of the characteristic polymorphic VT, torsades de pointes, seen in patients with congenital and acquired forms of LQTS (see Chapter 31). Although the genesis of ventricular arrhythmias in these patients

eFig. 3.2 Early Afterdepolarizations (EADs) and Cardiac Arrhythmias. Mixed focal reentrant polymorphic ventricular tachycardia as a result of EAD-mediated premature ventricular complexes (PVCs) arising from EAD islands in simulated two-dimensional homogeneous tissue. The tissue was paced from the left edge at a slow rate. Four successive voltage snapshots show an EAD (red in upper left quadrant) that generates a PVC (red blob). The PVC then initiates reentry by reentering (white arrow) the receding wave back of the region without EADs (blue blob). The voltage trace below from a representative cell shows multiple EADs followed by rapid tachycardia resulting from a mixture of triggered activity and reentry. (From Weiss JN, Garnkel A, Karagueuzian HS, et al. Early afterdepolarizations and cardiac arrhythmias. *Heart Rhythm*. 2010;7: 1891–1899.)

is still unclear, marked transmural dispersion of repolarization can create a vulnerable window for development of reentry. EADs arising from these regions can underlie the premature complexes that initiate or perpetuate the tachycardia.¹²

Structural heart disease. Structural heart disease such as cardiac hypertrophy and failure can also delay ventricular repolarization—so-called electrical remodeling—and predispose to arrhythmias related to abnormalities of repolarization. The abnormalities of repolarization in hypertrophy and failure are often magnified by concomitant drug therapy or electrolyte disturbances.²⁷

Properties of Early Afterdepolarizations

EAD-triggered arrhythmias exhibit rate dependence. In general, the amplitude of an EAD is augmented at slow rates when action potentials are longer in duration. Pacing-induced increases in rate shorten the action potential duration and reduce EAD amplitude. Action potential shortening and suppression of EADs with increased stimulation rate are likely the result of augmentation of delayed rectifier I_K and perhaps hastening of Ca^{2+} -induced inactivation of I_{CaL} . Once EADs have achieved a steady-state magnitude at a constant drive CL, any event that shortens the drive CL tends to reduce their amplitude. Hence the initiation of a single premature depolarization, which is associated with an acceleration of repolarization, will reduce the magnitude of the EADs that accompany the premature action potential; as a result, triggered activity is not expected to follow premature stimulation. The exception is when a long compensatory pause follows a premature ventricular complex. This situation can predispose to the development of an EAD and can be the mechanism of torsades de pointes in some patients with the LQTS. Thus EADs are more likely to trigger rhythmic activity when the spontaneous heart rate is slow because bradycardia is associated with prolongation of the QT interval and action potential duration (e.g., bradycardia- or pause-induced torsades de pointes). Similarly, catecholamines increase heart rate and decrease action potential duration and EAD amplitude, despite the effect of beta-adrenergic stimulation to increase I_{CaL} .

REENTRY

Basic Principles of Reentry

During each normal cardiac cycle, at the completion of normal cardiac excitation, the electrical impulse originating from the sinus node becomes extinct, and the subsequent excitation cycles originate from new pacemaker impulses. Physiological excitation waves vanish spontaneously after the entire heart has been activated because of the long duration of refractoriness in the cardiac tissue compared with the duration of the excitation period; therefore, after its first pass, the impulse, having no place to go, expires. Reentry occurs when a propagating impulse fails to die out after normal activation of the heart and persists to reexcite the heart after expiration of the refractory period. In pathological settings, excitation waves can be blocked in circumscribed areas, rotate around these zones of block, and reenter the site of original excitation in repetitive cycles. The wavefront does not extinguish but rather propagates continuously and thus continues to excite the heart because it always encounters excitable tissue.¹⁰

Reentrant tachycardia (also called reentrant excitation, reciprocating tachycardia, circus movement, or reciprocal or echo beats) is a continuous repetitive propagation of the activation wave in a circular path, returning to its site of origin to reactivate that site. Traditionally, reentry has been divided into two types: (1) anatomical reentry, when there is a distinct relationship of the reentry pathway with the underlying tissue structure; and (2) functional reentry, when reentrant circuits occur at random locations without clearly defined anatomical boundaries

Fig. 3.8 Models of Reentry. The solid area is completely refractory tissue, and mottled area is partially refractory. In anatomical reentry, the circuit is determined by structures or scar in the heart, and a portion of the circuit that has fully recovered excitability can be stimulated while it awaits the next cycle. However, in functional reentry, the rate is as rapid as it can be and still allow all portions of the circuit to recover.

BOX 3.1 Criteria for Diagnosis of Reentrant Tachycardia

1. Mapping activation in one direction around the continuous loop
2. Correlation of continuous electrical activity with occurrence of tachycardia
3. Correlation of unidirectional block with initiation of reentry
4. Initiation and termination by premature stimulation
5. Dependence of initiation of the arrhythmia on the site of pacing
6. Inverse relationship between the coupling interval of the initiating premature stimulus and the interval to the first tachycardia beat
7. Resetting of the tachycardia by a premature beat, with an inverse relationship between the coupling interval of the premature beat and the cycle length of the first or return beat of the tachycardia
8. Fusion between a premature beat and the tachycardia beat followed by resetting
9. Transient entrainment (with external overdrive pacing, the ability to enter the reentrant circuit and capture the circuit, resulting in tachycardia at the pacing rate with fused complexes)
10. Abrupt termination by premature stimulation
11. Dependence of initiation on critical slowing of conduction in the circuit
12. Similarity with experimental models in which reentry is proven and is the only mechanism of tachycardia

(Fig. 3.8). Although this distinction has a historical background and is useful for didactic purposes, both the anatomical and functional forms can coexist in a given pathological setting and share many common basic biophysical mechanisms.²⁸

The original three criteria for reentry proposed by Mines still hold true: (1) unidirectional block is necessary for initiation; (2) the wave of excitation should travel in a single direction around the pathway, returning to its point of origin and then restarting along the same path; and (3) the tachycardia should terminate when one limb of the pathway is cut or temporarily blocked. The 12 conditions that were proposed to prove or identify the existence of reentrant tachycardia in the EP laboratory are listed in Box 3.1.

Requisites of Reentry

Substrate

The initiation and maintenance of a reentrant arrhythmia require the presence of myocardial tissue with adjacent tissue or pathways having different EP properties, conduction, and refractoriness, and that they be joined proximally and distally, forming a circuit. These circuits can be stationary or can move within the myocardial substrate.

The reentrant circuit can be an anatomical structure, such as a loop of fiber bundles in the Purkinje system or accessory pathways, or a

Fig. 3.9 Reentry in the Wolff-Parkinson-White Syndrome. AV, Atrioventricular; ECG, electrocardiographic.

functionally defined pathway, with its existence, size, and shape determined by the EP properties of cardiac tissues in which the reentrant wavefront circulates. The circuit can also be an anatomical-functional combination. The cardiac tissue that constitutes the substrate for reentrant excitation can be located almost anywhere in the heart. The reentrant circuit can be a variety of sizes and shapes and can include different types of myocardial cells (e.g., atrial, ventricular, nodal, Purkinje) (Fig. 3.9).

Central Area of Block

A core of inexcitable tissue around which the wavefront circulates is required to sustain reentry. Without this central area of block, the excitation wavefront will not necessarily be conducted around the core of excitable tissue; rather, it could take a shortcut, permitting the circulating excitation wavefront to arrive early at the site where it originated. If it arrives sufficiently early, the tissue at the site of origination will still be refractory, and reentrant excitation will not be possible.

As mentioned earlier, the area of block can be anatomical, functional, or a combination of the two. Anatomical block is the result of a non-conductive medium in the center of the circuit, such as the tricuspid annulus in typical atrial flutter (AFL). Functional block at the center of a circuit occurs when there is block of impulses in otherwise excitable cardiac muscle. The central area of functional block develops during the initiation of the reentrant circuit by the formation of a line of block that most likely is caused by refractoriness. When the reentrant circuit forms, the line of block then is sustained by centripetal activation from the circulating wavefront that, by repeatedly bombarding the central area of block, maintains the state of refractoriness of this region. A combination of an anatomical and a functional central area of block

in the reentrant circuit has been described in some models of AFL such as the orifice of one or both venae cavae and an area of functional block continuous with or adjacent to either or both caval orifice(s). In addition, it has now been shown that a functional extension of an anatomical line of block can occur such that it plays a role in creating the necessary or critical substrate for reentry. Thus a surgical incision in the RA made to repair a congenital heart lesion can, under certain circumstances, develop a functional extension to one or both of the venae cavae, such that the substrate to create and sustain AFL develops.¹⁹

Unidirectional Conduction Block

Transient or permanent unidirectional block is usually a result of heterogeneity of EP properties of the myocardium and is essential for the initiation of reentry. The excitation wavefront propagating in the substrate must encounter unidirectional block; otherwise, the excitation wavefronts traveling down both limbs of the reentrant circuit will collide and extinguish each other.

Area of Slow Conduction

In a successful reentrant circuit, the wavefront of excitation must encounter excitable cells or the tachycardia will terminate. Therefore a condition necessary for reentry is the maintenance of excitable tissue ahead of the propagating wavefront. In other words, the tissue initially activated by the excitation wavefront should have sufficient time to recover its excitability by the time the reentrant wavefront returns. Thus conduction of the circulating wavefront must be sufficiently delayed in an alternate pathway to allow for expiration of the refractory period in the tissue proximal to the site of unidirectional block, and there must always be a gap of excitable tissue (fully or partially excitable) ahead

of the circulating wavefront (i.e., the length of the reentrant pathway must equal or exceed the reentrant wavelength; see later). This is facilitated by a sufficiently long reentrant pathway (which is especially important when conduction is normal along the reentrant path), sufficiently slow conduction in all or part of the alternative pathway (because sufficiently long pathways are usually not present in the heart), sufficient shortening of the refractory period, or a combination of these factors.

Critical Tissue Mass

An additional requisite for random reentry is the necessity of a critical mass of tissue to sustain the one or usually more simultaneously circulating reentrant wavefronts. Thus it is essentially impossible to achieve sustained fibrillation of ventricles of very small, normal, mammalian hearts and equally difficult to achieve sustained fibrillation of the completely normal atria of humans or smaller mammals.

Initiating Trigger

Another prerequisite for reentrant excitation to occur is often, but not always, the presence of an initiating trigger, which invokes the necessary EP milieu for initiation of reentry. Susceptible patients with appropriate underlying substrates usually do not suffer from incessant tachycardia because the different EP mechanisms required for the initiation and maintenance of a reentrant tachycardia are infrequently present at exactly the same time. However, changes in heart rate or autonomic tone, ischemia, electrolyte or pH abnormalities, or the occurrence of a premature depolarization can be sufficient to initiate reentrant tachycardia.

The trigger frequently is required because it elicits or brings to a critical state one or more of the conditions necessary to achieve reentrant excitation. In fact, premature depolarizations frequently initiate these tachyarrhythmias because they can cause slow conduction and unidirectional block. Thus a premature impulse initiating reentry can arrive at one site in the potential reentrant circuit sufficiently early that it encounters unidirectional block because that tissue has had insufficient time to recover excitability after excitation by the prior impulse. Furthermore, in the other limb of the potential reentrant circuit, the premature arrival of the excitation wavefront causes slow conduction or results in further slowing of conduction of the excitation wavefront through an area of already slow conduction. The resulting increase in conduction time around this limb of the potential reentrant circuit allows the region of unidirectional block in the tissue in the other limb activated initially by the premature beat to recover excitability. It should be noted that the mechanism causing the premature impulse can be different from the reentrant mechanism causing the tachycardia. Thus the premature impulse can be caused by automaticity or triggered activity.

Types of Reentrant Circuits

Anatomical Reentry

In anatomically determined circuits, a discrete inexcitable anatomical obstacle creates a surrounding circular pathway, resulting in a fixed length and location of the reentrant circuit. Because the length and location of the reentrant pathway are relatively fixed, the characteristics of the reentrant circuit are determined by the characteristics of the anatomical components of that circuit.¹⁰

A reentrant tachycardia is initiated when an excitation wavefront splits into two limbs after going around the anatomical obstacle and travels down one pathway and not the other, thus creating a circus movement. Tachycardia rates are determined by the wavelength and by the length of the reentrant pathway (the path length). The initiation and maintenance of anatomical reentry depend on conduction velocity and refractory period. Thus, as long as the extension of the refractory zone behind the excitation wave, the so-called wavelength of excitation,

is smaller than the entire length of the anatomically defined reentrant pathway, a zone of excitable tissue, the so-called excitable gap, exists between the tail of the preceding wave and the head of the following wave. In essence, circus movements containing an excitable gap are stable with respect to their frequency of rotation and can persist at a constant rate for hours. In the setting where the wavelength of excitation exceeds the path length, the excitation wavefront becomes extinct when it encounters the not yet recovered inexcitable tissue. A special case is present in the intermediate situation, when the head of the following wavefront meets the partially refractory tail of the preceding wavefront (i.e., the wavelength approximates the path length). This situation is characterized by unstable reentrant CLs and complex dynamics of the reentrant wavefront. There is often a long excitable gap associated with anatomical reentry.¹⁰

Anatomical circuits therefore are associated with ordered reentry. Examples of this type of reentry are atrioventricular reentrant tachycardia, atrioventricular nodal reentrant tachycardia, AFL, VT originating within the HPS (bundle-branch reentry VT), and post-MI VT.

Functional Reentry

In functionally determined circuits, the reentrant pathway depends on the intrinsic heterogeneity of the EP properties of the myocardium, not by a predetermined anatomical circuit (i.e., without involvement of an anatomical obstacle or anatomically defined conducting pathway). Such heterogeneity involves dispersion of excitability or refractoriness and conduction velocity, as well as anisotropic conduction properties of the myocardium.²⁹

Functional circuits typically tend to be small and unstable; the reentrant excitation wavefront can fragment, generating other areas of reentry. The location and size of these tachycardias can vary. The circumference of the leading circle around a functional obstacle can be as small as 6 to 8 mm and represents a pathway in which the efficacy of stimulation of the circulating wavefront is just sufficient to excite the tissue ahead, which is still in its relative refractory phase. Therefore conduction through the functional reentrant circuit is slowed because impulses are propagating in partially refractory tissue. Consequently, this form of functional reentry has a partially excitable gap. The reentry CLs are therefore significantly dependent on the refractory period of the involved tissue.²⁹

The mechanisms for functionally determined reentrant circuits include the leading circle type of reentry, anisotropic reentry, and spiral wave reentry. Functional circuits can be associated with ordered reentry (the reentrant circuit remains in the same place) or random reentry (the reentrant circuit changes size and location). Random reentry can occur when leading circle reentry causes fibrillation.

Leading circle concept. To explain the properties of a single functional reentrant circuit, Allesie and colleagues formulated the leading circle concept (see Fig. 3.8). It was postulated that during wavefront rotation in tissue without anatomical inexcitable obstacles, the wavefront impinges on its refractory tail and travels through partially refractory tissue. The interaction between the wavefront and the refractory tail determines the properties of functional reentry. In this model, functional reentry involves the propagation of an impulse around a functionally determined region of inexcitable tissue or a refractory core and among neighboring fibers with different EP properties. The tissue within this core is maintained in a state of refractoriness by constant centripetal bombardment from the circulating wavefront. The premature impulse that initiates reentry blocks in fibers with long refractory periods and conducts in fibers with shorter refractory periods and eventually returns to the initial region of block after excitability has recovered there. The impulse then continues to circulate around a central area that is kept refractory because it is bombarded constantly by wavelets propagating toward it from the circulating wavefront. This central area provides a

functional obstacle that prevents excitation from propagating across the fulcrum of the circuit.¹²

The leading circle was defined as “the smallest possible pathway in which the impulse can continue to circulate” and “in which the stimulating efficacy of the wavefront is just enough to excite the tissue ahead which is still in its relative refractory phase.” Thus the “head of the circulating wavefront is continuously biting its tail of refractoriness” and the length of the reentrant pathway equals the wavelength of the impulse; as a result, there is usually no fully excitable gap. Because the wavefront propagates through partially refractory tissue, the conduction velocity is reduced.²⁹

The velocity value and the length of the circuit depend on the excitability of the partially refractory tissue and on the stimulating efficacy of the wavefront, which is determined by the amplitude and upstroke velocity of the action potential and by the passive electrical properties of the tissue (e.g., gap junctional conductance). The partially refractory tissue determines the revolution time period. Because of the absence of a fully excitable gap, this form of reentry is less susceptible to resetting, entrainment, and termination by premature stimuli and pacing maneuvers. Leading circle reentry is thought to be the underlying mechanism of AF and VF and of at least some of the ventricular arrhythmias associated with acute ischemia.

Anisotropic reentry. Anisotropy refers to directionally dependent conduction velocity. Isotropic conduction is uniform in all directions; anisotropic conduction is not. Anisotropy is a normal feature of heart muscle and is related to the differences in longitudinal and transverse conduction velocities, which are attributable to the lower resistivity of myocardium in the longitudinal (parallel to the long axis of the myocardial fiber bundles) versus the transverse direction (see eFig. 1.1). Anisotropy in myocardium composed of tissue with structural features different from those of adjacent tissue results in heterogeneity in conduction velocities and repolarization properties (see later discussion), which can lead to conduction slowing or block, thereby setting the stage for reentry (referred to as anisotropic reentry).

Unlike the functional characteristic that leads to the leading circle type of reentry (differences in refractoriness in adjacent areas caused by local differences in membrane properties), the functional characteristic that is important in functional reentry caused by anisotropy is the difference in effective axial resistance to impulse propagation dependent on fiber direction. In its pure form, the unidirectional conduction block and slow conduction in the reentrant circuit result from anisotropic, discontinuous propagation, and there is no need for variations in membrane properties, such as regional differences in refractoriness or depression of the resting and action potentials.

Anisotropic circuits are elliptical or rectangular because of the directional differences in conduction velocities, with the long axis of the ellipse in the fast longitudinal direction and a central line of functional block parallel to the long axis of fibers. Circuits with this shape can have a smaller dimension than circular circuits, such as the leading circle. Reentrant circuits caused by anisotropy also can occur without well-defined anatomical pathways and may be classified as functional.

Anisotropic reentrant circuits usually remain in a fixed position and cause ordered reentry. The degree of anisotropy (i.e., the ratio of longitudinal to transverse conduction velocity) varies in different regions of the heart, and the circuit can reside only in a region in which the conduction transverse to the longitudinal axis is sufficiently slow to allow reentry. Stability of anisotropic reentrant circuits is also assisted by the presence of an excitable gap, which does not occur in the leading circle functional circuit. The excitable gap is caused by the sudden slowing of conduction velocity and a decrease in the wavelength of excitation as the reentrant impulse turns the corner from the fast longitudinal direction to the slow transverse direction and from the slow

transverse direction to the fast longitudinal direction. Anisotropic reentry is typically initiated by a premature stimulus that blocks in the direction of propagation parallel to the long axis of the cells and then propagates slowly in the transverse direction of fiber orientation because of high axial resistance (see later).

Anisotropic reentry can potentially provide the substrate for sustained VT that occurs in the epicardial border zone region of healed infarcts, where viable normal myocytes are intermingled with islands of fibrous connective tissue that separate muscle fiber bundles preferentially in the longitudinal direction and decrease the density of side-to-side junctional connections, therefore creating nonuniform anisotropy.

Figure-of-8 reentry. The model of “figure-of-8” or “double-loop” reentry involves two concomitant excitation wavefronts circulating in opposite directions, clockwise and counterclockwise, around a long line of functional conduction block rejoining on the distal side of the block. The wavefront then breaks through the arc of block to reexcite the tissue proximal to the block. The single arc of block is thus divided into two, and reentrant activation continues as two circulating wavefronts that travel clockwise and counterclockwise around the two arcs in a pretzel-like configuration. This form of reentry has been shown in atrial and ventricular myocardia.¹²

Figure-of-8 reentry can also occur when two adjacent anatomical obstacles are located transverse to the direction of propagation, with only a small gap (isthmus) of low excitability in between. The activation wavefront blocks anterogradely in the gap and bifurcates into two distinct activation wavefronts skirting the two anatomical obstacles in clockwise and counterclockwise directions. The two wavefronts coalesce at the opposite side of the gap; the convergence increases the source/sink ratio, allowing the activation to propagate retrogradely through the gap and initiate reentry (Fig. 3.10; Video 3.1).^{30,31}

Fig. 3.10 Figure-of-8 Reentry. (A) Electrocardiographic and intracardiac recordings from a left ventricular mapping catheter (*Map*) and the right ventricle (*RV*) are shown during scar-based ventricular tachycardia. (B) A stylized tachycardia circuit is shown in which propagation proceeds through a central common pathway (*small arrows and asterisk*) constrained by scar or other barriers and then around the outside of these same barriers. Activation in the circuit during electrical diastole is shaded (also in A).

Video 3.1 Reentrant Ventricular Tachycardia. Optical Mapping. Optical mapping of sustained reentrant ventricular tachycardia in an isolated wedge of ventricular wall from a dog with a previous infarct. The presence of transmural dispersion of excitability and refractoriness provided the substrate for transmural reentry during epicardial stimulation. Activation initiated in the epicardium blocks laterally in the epicardium, conducts transmurally to the endocardium, propagates laterally in the endocardium, and returns to the epicardium to complete reentrant loops (figure-of-8 reentry).

Reflection. Reflection is a special subclass of reentry in which the excitation wavefront does not require a circuit but appears to travel back and forth in a linear segment of tissue (e.g., trabecula or Purkinje fiber) containing an area of conduction block (see Fig. 3.8). In such a situation an action potential propagates toward, but not through, the inexcitable zone. Subsequently, an electrotonic current conducts passively (i.e., without eliciting an action potential) through the inexcitable zone toward the distal portion of the pathway. If the inexcitable zone is sufficiently small and the magnitude of the electrotonic current is sufficiently large, the segment of tissue distal to the blocked area will be excited (i.e., an action potential is elicited) but with a significant delay. The action potential generated in the distal portion of the pathway will then cause electrotonic current to flow back through the inexcitable zone toward the proximal region. Provided the proximal portion of the conduction pathway recovers quickly enough, this current may be sufficient to elicit a second action potential on the proximal side of the inexcitable zone, which propagates in the opposite direction to the first action potential, thus giving the appearance that the inexcitable zone has reflected the initial action potential.

A different model of reflection (“expansion-type reflection”) was recently demonstrated, whereby the activation wavefront propagates through a narrow isthmus region to stimulate a larger number of cells in the expanded distal region. The source-sink mismatch causes the direction of electrotonic currents to be reversed, and the delayed depolarization in the distal region provides enough time to generate an action potential in the proximal region, and hence acts as the source of reflection.^{1,32}

Because reflection can occur within areas of tissue as small as 1 to 2 mm², it is likely to appear of focal origin. Its identification as a mechanism of arrhythmia may be difficult even with very high spatial resolution mapping of the electrical activity of discrete sites. Reflections may be responsible for premature cardiac contractions and may initiate fatal cardiac arrhythmias such as VT and VF.

Phase 2 reentry. As discussed in Chapter 1, substantial differences in the expression levels of ion channels underlie the substantial heterogeneity in action potential duration and configuration between cardiomyocytes across the ventricular wall. Heterogeneity in the distribution of the transient outward I_K (I_{to}) channels across the myocardial wall, being more prominent in ventricular epicardium than endocardium, results in the shorter duration and the prominent phase 1 notch and the “spike and dome” morphology of the epicardial action potential as compared with the endocardium. The resultant transmural voltage gradient during the early phases (phases 1 and 2) of the action potential is thought to be responsible for the inscription of the J wave on the surface ECG (see Fig. 31.9). A significant outward shift of currents, secondary to either a decrease in the inward currents (I_{Na} and I_{CaL}) or an increase in the outward I_K (I_{to} , I_{Kr} , I_{Ks} , I_{KACH} , I_{KATP}), or both, can cause partial or complete loss of the dome of the action potential in the epicardium that leads to exaggeration of transmural voltage gradient and dispersion of repolarization between the epicardium and endocardium. The type of the ion current affected and its regional distribution in the ventricles determine the particular phenotype (including the Brugada syndrome, early repolarization syndrome, hypothermia-induced ST segment elevation, and infarction-induced ST segment elevation).¹⁰

In this setting the phase 2 dome (plateau) of the action potential can potentially propagate from regions where it is preserved (midmyocardium and endocardium) to regions where it is abolished (epicardium), thus causing local reexcitation (phase 2 reentry) and the generation of a closely coupled extrasystole that, in turn, can initiate VT or VF (see Fig. 31.10).

Spiral wave (rotor) activity. The leading circle concept was based on properties of impulse propagation in a one-dimensional tissue that forms a closed pathway (e.g., a ring). The concept was a major breakthrough in the understanding of the mechanisms of reentrant excitation. However, it became evident that these considerations alone do not fully describe wave rotation in two- and three-dimensional cardiac tissue.^{10,33}

Spiral waves typically describe reentry in two dimensions. The three-dimensional representation of the spiral wave is called a “scroll wave.” The center of the spiral wave is called the core, and the distribution of the core in three dimensions is referred to as the filament, which is formed by the revolving trajectory of the spiral tip. The term *rotor* initially described the rotating source, and the spiral wave defined the shape (i.e., curvature) of the wave emerging from the rotating source. In many publications, this difference has been blurred, and terms used in the literature include *rotors*, *vortices*, and *reverberators*.^{12,34,35}

Propagation of two- and three-dimensional waves depends on wavefront curvature, a property that is not present in one-dimensional preparations (Fig. 3.11). The curvature of an activation wavefront influences the source-sink balance; convex wavefronts have a smaller source and a larger sink, whereas flat wavefronts have source-sink balance. As a result, a planar wavefront propagates faster than a convex wavefront. As curvature of a wavefront increases, conduction velocity decreases; with sufficient curvature, propagation fails. Because the maximal velocity of a convex rotating wavefront can never exceed the velocity of a planar wavefront and the period of rotation remains constant in a stable rotating wave, the velocity has to decrease from the periphery (where the highest value corresponds to linear velocity) to the center of a rotating wave. As a consequence, any freely rotating wave in an excitation-diffusion system has to assume a spiral shape.¹⁹

The curvature of the rotating spiral waves progressively increases (and the conduction velocity progressively decreases) toward the tip near the spiral center (the core). At the tip the convex curvature reaches a critical value, forming a singularity point (rotor) that organizes the reentrant spiral wave activity. At the singularity point the curvature is so extreme that makes it impossible for the activity to invade the core. Therefore, instead of moving farther into the center, the rotor spins in the myocardium at high speed around a core of unexcited (rather than refractory) tissue, organizing the electrical activity around it in the form of spiral waves.^{28,34,35}

A prominent curvature of the spiral wave is generally encountered following a wave break, a situation in which a planar wave encounters an anatomical or functional obstacle with sharp edges and breaks up into two or more daughter waves (so-called vortex shedding). Because it has the greatest curvature, the broken end of the wave moves most slowly along a complex trajectory and radiates waves into the surrounding medium. Activation waves propagate radially from the rotor core producing a spiral wave. If the edge of this spiral wave encounters unexcitable tissue, then it will break, giving rise to daughter spirals. As the spinning rate increases, the turbulence and spiral wave fractionation around the rotor increase. This can exhibit complex reentry patterns in which multiple meandering spiral waves divide to form daughter waves while others are simultaneously annihilated, resulting in disorganized electrical activity.^{28,30,34}

Because the slow activation by a rotor is not dependent on conduction in relatively refractory myocardium, an excitable gap can exist, despite the functional nature of reentry. This type of functional reentrant excitation does not require any inhomogeneities of refractory periods as in leading circle reentry, inhomogeneities in conduction properties as in anisotropic reentry, or a central obstacle, whether functional or anatomical. The heterogeneity that allows initiation can result from a previous excitation wave and the pattern of recovery from that wave. Even though nonuniform dispersions of refractoriness or anisotropy

Fig. 3.11 Rotors and Spirals, Basic Concepts. (A) Schematic representation of reentry around a ringlike anatomic obstacle where the wavelength (black) is shorter than the path length, allowing for a fully excitable gap (white). (B) Leading circle reentry, in which activation propagates around a functionally refractory core. (C) Color phase map of a two-dimensional spiral wave, along with the rotor tip at the center (asterisk). (D) Schematic of a three-dimensional scroll wave. (E) Snapshot of the spiral wave: electrotonic effects of the core decrease conduction velocity (arrows), action potential duration (representative examples shown from positions 1, 2, and 3), and wavelength (the distance from the wavefront [black line] to the wave tail [dashed line]). Conduction velocity decreases and wavefront curvature becomes more pronounced, near the rotor, which is a phase singularity at the point where the wavefront and the wave tail meet (asterisk). (F) Computer simulation of reentry. *Top*, Snapshot of the transmembrane voltage distribution during simulated reentry in chronic atrial fibrillation conditions in a two-dimensional sheet incorporating human atrial ionic math models. *Bottom*, Snapshot of inactivation variables of sodium current (h_j) during reentry. (From Pandit SV, Jalife J. Rotors and the dynamics of cardiac fibrillation. *Circ Res*. 2013;112:849–862.)

are not necessary for the initiation of reentrant excitation caused by rotors in excitable media, the myocardium, even when normal, is never homogeneous, and anisotropy and anatomical obstacles can modify the characteristics and spatiotemporal behavior of the spiral. Because cells at the core are unexcited, a voltage gradient develops and establishes a continuous electronically mediated repolarizing influence on excited cells in the immediate core vicinity, shortening their action potential duration.^{28,35}

The location of the rotor can occur wherever the second stimulated excitation encounters the wake of the first excitation with the appropriate characteristics. Rotors can be stationary, continuously drift or migrate away from their origin, or anchored, initially drifting and then becoming stationary by anchoring to an anatomical obstacle. This depends on the electrical (e.g., wavelength) and structural (e.g., fibrosis) properties of the tissue in which they occur.²⁸

In the heart, both two-dimensional spiral waves and three-dimensional scroll waves have been implicated in the mechanisms of reentry in atrial and VT and fibrillation.¹⁹ Monomorphic VT results when the spiral wave is anchored within the ventricular myocardium and cannot drift away from its origin. In contrast, a polymorphic VT, such as the torsades de pointes encountered with LQTS, is thought to be caused by a meandering or drifting spiral wave. VF seems to be the most complex representation of rotating spiral waves in the heart. VF develops when the single spiral wave responsible for VT breaks up, leading to the development of multiple spirals that are continuously extinguished and recreated.^{34–36}

Excitable Gaps in Reentrant Circuits

Wavelength Concept

The *wavelength* is defined as the product of the conduction velocity of the circulating excitation wavefront and the refractory period of the tissue in which the excitation wavefront is propagating. The wavelength quantifies how far the impulse travels relative to the duration of the refractory period. The wavelength of the reentrant excitation wavefront must be shorter than the length of the pathway of the potential reentrant circuit for reentrant excitation to occur; that is, the impulse must travel a distance during the refractory period that is less than the complete reentrant path length to give myocardium ahead of it sufficient time to recover excitability. Slowing of impulse conduction or shortening of refractoriness shortens the wavelength and increases the excitable gap.

For almost all clinically important reentrant arrhythmias resulting from ordered reentry and in the presence of uniform, normal conduction velocity along the potential reentrant pathway, the wavelength would be too long to permit reentrant excitation. Thus almost all these arrhythmias must have, and do have, one or more areas of slow conduction as a part of the reentrant circuit. The associated changes in conduction velocity, as well as associated changes in refractory periods, actually cause the wavelength to change in different parts of the circuit. However, the presence of one or more areas of slow conduction permits the average wavelength of reentrant activation to be shorter than the path length.

The wavelength concept is a good predictive parameter of arrhythmia inducibility. A decrease in conduction velocity or shortening of

refractoriness results in a decrease in the wavelength or lessening of the amount of tissue needed to sustain reentry. This situation favors initiation and maintenance of reentry. In contrast, an increase in conduction velocity or prolongation of refractoriness prolongs the wavelength of excitation, and in this situation a larger anatomical circuit is necessary to sustain reentry. If a larger circuit is not possible, initiation or maintenance of tachycardia cannot occur.

Excitable Gaps

The excitable gap in a reentrant circuit is the region of excitable myocardium that exists between the head of the reentrant wavefront and the tail of the preceding wavefront and, at any given time, is no longer refractory (i.e., is capable of being excited) if the excitation wavelength is shorter than the length of the reentrant circuit (Fig. 3.12).

The occurrence of an excitable gap is dependent on the recovery of excitability of the myocardium from its previous excitation by the reentrant wavefront. A fully excitable gap is defined as the segment of the reentrant circuit in which the tail of the preceding wavefront does not affect the head and velocity of the following wavefront (i.e., absence of head-tail interaction). A partially excitable gap is defined as the zone where the rotating wave can be captured by local stimulation in the presence of head-tail interaction. Although the excitable gap denotes a length of a segment within the reentrant circuit, the fully or partially excitable period denotes the time period during which a segment within the reentrant circuit is fully or partially excitable, respectively (see Fig. 3.12).

There are two different measurements of the excitable gap. The spatial excitable gap is the distance (in millimeters) of excitability occupied at any moment of time in the circuit ahead of the reentrant wavefront. On the other hand, the temporal excitable gap is the time interval (in milliseconds) of excitability between the head of activation of one impulse and the tail of refractoriness of the prior impulse. Both the spatial and temporal gaps can be composed of partially excitable or fully excitable myocardium, depending on the time interval between successive excitations of the circuit. The size of the spatial gap and the duration of the temporal gap vary in different parts of the circuit as the wavelength of the reentrant impulse changes because of changes in conduction velocity, refractory periods, or both.

The characteristics of the excitable gap can be different in different types of reentrant circuits. Many anatomically determined reentrant circuits have large excitable gaps with a fully excitable component, although the gap can sometimes be only partially excitable. On the other hand, functional reentrant circuits caused by the leading circle

mechanism have very small gaps that are only partially excitable, although parts of some functionally determined reentrant circuits (anisotropic reentrant circuits) can have fully excitable gaps. An excitable gap has been shown to occur during AF, VF, and AFL; these are examples of arrhythmias caused by functional reentrant mechanisms, possibly including spiral waves. The relationship between the excitable gap and the excitable period can be complex if the velocity of propagation changes within the reentry circuit.

The existence and extent of an excitable gap in a reentrant circuit have important implications. The presence of an excitable gap enables modulation of the frequency of a reentrant tachycardia by a locally applied stimulus or by field stimulation; the longer the excitable gap, the more likely an extrastimulus will be able to enter the reentrant circuit and reset or terminate the arrhythmia. Termination of arrhythmias by stimulation would be expected to be much more difficult when the reentrant circuit has only a small partially excitable gap. In addition, the excitable gap can influence the effects of drugs on the reentrant circuit, so that reentry with a partially excitable gap and mainly functional components may respond more readily to drugs that prolong repolarization, without slowing conduction. In contrast, fixed anatomical reentry with a large excitable gap responds to drugs that decrease conduction velocity, preferentially at pivot points.

The properties of the excitable gap influence the characteristics of arrhythmias caused by reentry. Arrhythmias caused by leading circle reentry, in which the wavefront propagates in the just-recovered myocardium of the refractory tail and in which there is only a small partially excitable gap, are inherently unstable and often terminate after a short period or go on to fibrillation. On the other hand, the reentrant wavefront in anatomical and nonuniform anisotropic reentry circuits generally is not propagating in myocardium that has just recovered excitability, and the excitable gap can be large. This property can contribute to the stability of these reentrant circuits.

Resetting Reentrant Tachycardias

Basic Principles of Resetting

Resetting is the interaction of a premature wavefront with a tachycardia, resulting in either advancement (acceleration) or delay of the subsequent tachycardia beat. The extrastimulus is followed by a pause that is less (or more) than fully compensatory before resumption of the original rhythm. The tachycardia complexes that return first should have the same morphology and CL as the tachycardia before the extrastimulus, regardless of whether single or multiple extrastimuli are used. The resetting phenomenon can easily be recognized by comparing the intervals encompassing the extrastimuli with the tachycardia cycle length (TCL). If they differ from twice the TCL (in the case of a single extrastimulus) or from 3 times the TCL (in the case of double extrastimuli) the tachycardia has been reset.^{37,38}

The introduction of a single extrastimulus (S_2) during a tachycardia yields a return cycle (S_2X_3) if the tachycardia is not terminated (Fig. 3.13). If S_2 does not affect the arrhythmogenic focus, the coupling interval (X_1S_2) plus the return cycle (S_2X_3) will be equal to twice the tachycardia cycle ($2 \times [X_1X_1]$); that is, a fully compensatory pause will occur. Resetting of the tachycardia occurs when a less than fully compensatory pause occurs. In this situation, $X_1S_2 + S_2X_3$ will be less than $2 \times (X_1X_1)$, as measured from the surface ECG. TCL stability should be taken into account when the return cycle is measured. To account for any TCL instability, at least a 20-millisecond shortening of the return cycle is required to demonstrate resetting.

When more than a single extrastimulus is used, the relative prematurity should be corrected by subtracting the coupling interval or intervals from the spontaneous tachycardia cycles when the extrastimuli are delivered.

Fig. 3.12 Excitable Gap of Recovered Tissue in Anatomically Determined Reentry.

Fig. 3.13 Response of Tachycardia to a Single Extrastimulus (S_2). The tachycardia cycle length is $[X_1X_1]$. The coupling interval of the extrastimulus is $[X_1S_2]$. The return cycle length of the first complex of tachycardia after the extrastimulus is $[S_2X_3]$. In the top portion of the figure, the extrastimulus does not affect the tachycardia circuit, and a compensatory pause occurs. Resetting (i.e., advancement) of the tachycardia is shown at the bottom of the figure. (From Frazier DW, Stanton MS. Resetting and transient entrainment of ventricular tachycardia. *Pacing Clin Electrophysiol.* 1995;18:1919.)

To reset a reentrant tachycardia, the stimulated wavefront must reach the reentrant circuit, encounter excitable tissue within the circuit (i.e., enter the excitable gap of the reentrant circuit), collide in the antidromic (retrograde) direction with the previous tachycardia impulse, and continue in the orthodromic (anterograde) direction to exit at an earlier than expected time and perpetuate the tachycardia (Fig. 3.14). If the extrastimulus encounters fully excitable tissue, which commonly occurs in reentrant tachycardias with large excitable gaps, the tachycardia will be advanced by the extent that the stimulated wavefront arrives at the entrance site prematurely. If the tissue is partially excitable, which can occur in reentrant tachycardias with small or partially excitable gaps or even in circuits with large excitable gaps when the extrastimulus is very premature, the stimulated wavefront will encounter some conduction delay in the orthodromic direction within the circuit (see Fig. 3.14). Therefore the degree of advancement of the next tachycardia beat depends on both the degree of prematurity of the extrastimulus and the degree of slowing of its conduction within the circuit. The reset tachycardia beat consequently can be early, on time, or delayed.^{37,38}

Termination of the tachycardia occurs when the extrastimulus collides with the preceding tachycardia impulse antidromically and blocks in the reentrant circuit orthodromically (see Fig. 3.14). This occurs when the extrastimulus enters the reentrant circuit early in the relative refractory period; it fails to propagate in the anterograde direction because it encounters absolutely refractory tissue. In the retrograde direction, it encounters increasingly recovered tissue and can propagate until it encroaches on the circulating wavefront and terminates the arrhythmia.

Resetting does not require that the pacing site be located within the reentrant circuit. However, the closer the pacing site is to the circuit, the less premature a single extrastimulus can be and reach the circuit without being extinguished by collision with a wave emerging from the circuit. The longest coupling interval for an extrastimulus to be able to reset a reentrant tachycardia depends on (1) the TCL; (2) the duration of the excitable gap of the tachycardia; (3) refractoriness at the pacing site; and (4) the conduction time from the pacing site to the reentrant circuit.

Fig. 3.14 Response of Reentrant Tachycardia to Premature Stimulation. (A) Schematic representation of the reentrant circuit is illustrated with separate entrance and exit sites. During tachycardia, a wavefront is shown propagating through the tissue of the reentrant circuit (arrow). The dark portion of the arrow represents fully refractory tissue, and the fading portion represents partially refractory tissue. (B) A premature stimulus (Stim) introduced during the tachycardia results in a wavefront of depolarization (red arrow), which enters the reentrant circuit and conducts anterogradely over fully excitable tissue while it collides retrogradely with the already propagating wavefront (blue arrow). The premature wavefront (red arrow) then propagates around the circuit to the exit site, thus leading to the less than compensatory pause and resetting of the tachycardia. (C) A more premature extrastimulus (Stim) results in a wavefront of depolarization (red arrow), which enters the circuit at a time when it collides retrogradely with the previously propagating wavefront (blue arrow) and encounters anterograde tissue incapable of sustaining further propagation. As a result, circus movement in the circuit is extinguished, and tachycardia terminates. (From Rosenthal ME, Stamato NJ, Almendral JM, et al. Coupling intervals of ventricular extrastimuli causing resetting of sustained ventricular tachycardia secondary to coronary artery disease: relation to subsequent termination. *Am J Cardiol.* 1988;61:770.)

When refractoriness of the intervening tissue between the pacing site and the reentrant circuit limits the ability of an extrastimulus to reach the reentrant circuit with adequate prematurity, the use of double extrastimuli can be helpful. The first extrastimulus, although it does not reset the tachycardia, it does shorten the local refractory period at the stimulus site and reverse the activation sequence in part of the intervening tissue, allowing the second extrastimulus to access and interact with the reentrant circuit with a greater degree of prematurity at comparable coupling intervals. Another advantage of using double extrastimuli is that it allows the longest potential coupling interval of the second extrastimulus to be delivered following the first (conditioning) extrastimulus, so that it interacts with the circuit with the lowest possible prematurity.^{37,39}

Resetting zone and excitable gap. For an extrastimulus to be able to reset the reentrant circuit, it has to penetrate the circuit during its excitable gap. The difference between the longest and shortest coupling intervals resulting in resetting is defined as the *resetting interval* or *resetting zone*. Thus the coupling intervals over which resetting occurs, the resetting zone, can be considered a measure of the duration of the temporal excitable gap existing in the reentrant circuit. Hence the entire

extent of the fully excitable gap would be the zone of coupling intervals from the onset of tachycardia resetting until tachycardia termination. However, the excitable gap can be underestimated by using only a single extrastimulus or by using single or double extrastimuli in the absence of tachycardia termination by the extrastimuli.³⁷

All tachycardias reset by a single extrastimulus can be reset by double extrastimuli, unless tachycardia termination occurs. Double extrastimuli produce resetting over a longer range of coupling intervals and should therefore be used to characterize the excitable gap of the reentrant circuit more fully. During EP testing, only the temporal excitable gap of the entire circuit can be evaluated. It is impossible to assess the conduction velocity and refractoriness at any point in the circuit, which certainly must vary, with available technology.

Return cycle. The return cycle is the time interval from the resetting stimulus to the next excitation of the pacing site by the new orthodromic wavefront. This corresponds to the time required for the stimulated impulse to reach the reentrant circuit, conduct through the circuit, exit the circuit, and travel back to the pacing site. The noncompensatory pause following the extrastimulus and the return cycle are typically measured at the pacing site; however, they may also be measured to the onset of the tachycardia complex on the surface ECG.

When the return cycle is measured from the extrastimulus producing resetting to the onset of the first return tachycardia complex on the surface ECG, conduction time into the tachycardia circuit is incorporated into that measurement. Conduction time between the pacing site and the tachycardia circuit may or may not be equal to that from the circuit to the pacing site. Differences in location of the site of stimulation, as well as the tachycardia circuit entrance and exit, can result in differences in conduction time to and from the pacing site.

Orthodromic and antidromic resetting

Orthodromic resetting. Orthodromic resetting occurs when the premature stimulus traverses the reentrant circuit, including the zone of slow conduction, in the same direction as the spontaneous tachycardia impulse and with an identical exit site. Intracardiac areas that are orthodromically reset are advanced by the premature extrastimulus but retain the same morphology because they are activated from the impulse emerging from the same reentrant circuit exit site. The conduction interval from the pacing stimulus to the orthodromically captured electrogram exceeds the TCL by the time required for the extrastimulus to travel from the pacing site to the reentrant circuit. Thus an orthodromic resetting response implies that the pacing site is located proximal to a region of slow conduction in the reentry circuit and that the recording site is located distal to this region. The ability to demonstrate orthodromic resetting is critically dependent on the location of pacing and recording electrodes relative to the region of slow conduction in the circuit. Therefore failure to demonstrate an orthodromic resetting response does not exclude reentry with an excitable gap as a possible tachycardia mechanism.³⁷

Antidromic resetting. Antidromic resetting occurs when intracardiac sites are directly captured by the premature stimulus without traversing the reentrant circuit and the zone of slow conduction. Therefore antidromic resetting of intracardiac sites occurs with a conduction interval from the pacing stimulus to the captured electrogram that is less than the TCL and with differing morphology of the captured as compared with the spontaneous electrogram. Although demonstration of an antidromic resetting response can indicate a tachycardia mechanism other than reentry, an antidromic resetting pattern can also be observed during reentry with an excitable gap if the pacing site is located distal to a region of slow conduction in the reentry circuit. Conversely, if the recording sites are located in regions activated proximal to a region of slow conduction, an antidromic resetting response will be observed.

Resetting Response Curves

Response patterns during resetting are characterized by plotting the coupling interval of the extrastimulus producing resetting versus the return cycle measured at the pacing site. Alternatively, the return cycle is measured to the onset of the first tachycardia complex following stimulation on the surface ECG; then, qualitatively similar but quantitatively different response curves are obtained. Demonstration of a noncompensatory pause following the extrastimulus is required, and the interval encompassing the extrastimulus should be 20 or more milliseconds earlier than the expected compensatory pause following a single extrastimulus and 20 or more milliseconds less than three TCLs when double extrastimuli are used. As always, it is important to establish the stability of TCL before assessing any perturbation in tachycardia presumed to be caused by resetting.^{37,38}

Four resetting response patterns are possible (Fig. 3.15):

1. Flat response pattern: The return cycle is constant (less than a 10-millisecond difference) over a 30-millisecond range of coupling intervals.

Fig. 3.15 Mechanisms of Various Resetting Response Patterns. (A) Schemas of three types of resetting response curves. (B) A theoretical mechanism of resetting patterns in response to extrastimuli at coupling intervals of X and X-50 milliseconds. The reentrant circuit is depicted as having a separate entrance and exit in each pattern. Each tachycardia wavefront is followed by a period of absolute refractoriness (blue arrow), which is then followed by a period of relative refractoriness (fading tail of the arrow) of variable duration. On the left side, a flat curve results when the stimulated wavefront reaches the tachycardia circuit and finds a fully excitable gap between the head and tail of the tachycardia wavefront. The gap is still fully excitable at a coupling interval of X-50. Therefore the conduction time from the entrance to exit is the same. An increasing curve is shown in the middle; this results when the initial stimulated wavefront enters the reentrant circuit when the excitable gap is partially refractory. The curve continues to increase at a coupling interval of X-50 because the tissue is still in a relative refractory state. A mixed curve (right side) results when the less premature extrastimuli find the reentrant circuit fully excitable, whereas the more premature one (at coupling intervals of X-50) finds it in the relative refractory period. (From Josephson ME. Recurrent ventricular tachycardia. In: Josephson ME, ed. *Clinical Cardiac Electrophysiology*. 3rd ed. Philadelphia: Lippincott Williams & Wilkins; 2004:425–610.)

2. Increasing response pattern: The return cycle increases as the coupling interval increases.
3. Decreasing response pattern: The return cycle decreases as the coupling interval increases.
4. Mixed response pattern: This pattern meets the criteria for a flat response at long coupling intervals and for an increasing response at shorter coupling intervals.

Triggered rhythms secondary to DADs usually have a flat or decreasing response. A flat response can be observed in automatic, triggered, or reentrant rhythms.

Occasionally, a response pattern to a single extrastimulus cannot be characterized because resetting occurs over too narrow a range of coupling intervals as a result of significant variability of the baseline TCL or of variability in the return cycle. In all cases in which a single extrastimulus resets the tachycardia, double extrastimuli from the same pacing site produce an identical or expected resetting curve. Thus, if a single extrastimulus produces a flat curve, double extrastimuli will produce a flat or mixed curve. If a single extrastimulus produces an increasing or mixed curve, double extrastimuli will produce the same curve.

The types of resetting curves can vary depending on the site of stimulation. Extrastimuli from different pacing sites likely engage different sites in the reentrant circuit that are in different states of excitability or refractoriness and therefore result in different conduction velocities and resetting patterns.

Flat response curves in reentrant rhythms. A flat resetting curve implies the presence of a fully excitable gap within the reentrant circuit over a range of coupling intervals. The total duration of the excitable gap should exceed the range of coupling intervals that produce resetting with a flat response. Large excitable gaps are more likely to result in flat response curves, because the increasingly premature extrastimuli are less likely to encroach on the trailing edge of refractoriness and encounter decremental conduction (see Fig. 3.15). The flat return cycle also suggests the presence of fixed sites of entrance and exit from the circuit and fixed conduction time from the stimulation site through the reentrant circuit over a wide range of coupling intervals.

If a single extrastimulus produced resetting with a flat response, the response to double extrastimuli would also be flat. However, because the use of double extrastimuli allows engagement of the reentrant circuit at relatively long coupling intervals with greater prematurity, resetting will begin at longer coupling intervals and will continue over a greater range of coupling intervals than observed with a single extrastimulus. Therefore double extrastimuli can produce a flat and then increasing response curve.

Increasing response curves in reentrant rhythms. Increasing resetting curves result from progressively longer return cycles in response to increasingly premature extrastimuli and indicate a zone of decremental slow conduction, usually located within the reentrant circuit. The most probable mechanism underlying the decremental conduction is encroachment of the advancing wavefront from the premature extrastimuli on an increasingly more refractory tissue within the reentrant circuit, most likely within the zone of slow conduction (see Fig. 3.15). This response pattern is possible only for reentrant arrhythmias and is not observed in triggered or automatic rhythms.

Mixed response curves in reentrant rhythms. In a mixed response curve, the initial coupling intervals demonstrate a flat portion of the curve of variable duration (but less than 30 milliseconds), followed by a zone during which the return cycle increases (see Fig. 3.15). Occasionally, a flat curve is seen with a single extrastimulus; it is only by using double extrastimuli that an increasing response can be observed.

Decreasing response curves in reentrant rhythms. Decreasing reset curves are not observed in reentry but can be seen in triggered

rhythms, although flat responses are the most common response for triggered activity. The return cycle in triggered activity is typically 100% to 110% of the TCL.

Resetting With Fusion

Fusion of the stimulated impulse can be observed on surface ECG or intracardiac recordings if the stimulated impulse is intermediate in morphology between a fully paced complex and the tachycardia complex. The ability to recognize ECG fusion requires a significant mass of myocardium to be depolarized by both the extrastimulus and the tachycardia. With early extrastimuli, the paced antidromic wavefront captures all or most of the myocardium prior to the orthodromic wavefront of the tachycardia impulse exiting from the reentrant circuit. Thus no ECG fusion is present, although resetting can occur. With later coupled extrastimuli, the orthodromic wavefront exits from the reentrant circuit, thus capturing a certain portion of myocardium before colliding with the paced antidromic wavefront. In this situation, ECG fusion occurs. Resetting with ECG fusion requires wide separation of the entrance and exit of the reentrant circuit, with the stimulus wavefront preferentially engaging the entrance.³⁷

If presystolic activity in the reentrant circuit is recorded before delivery of the extrastimulus that resets the tachycardia, one must consider this to represent local fusion (eFig. 3.3). Thus an extrastimulus that is delivered after the onset of the tachycardia complex and enters and resets the circuit always demonstrates local fusion. Resetting with local fusion and a totally paced complex morphology provides evidence that the reentrant circuit is electrocardiographically small.

The farther the pacing site from the reentrant circuit, the less likely resetting with ECG fusion will occur because the extrastimulus should be delivered at a shorter coupling interval to reach the circuit with adequate prematurity. Consequently, the stimulated impulse is more likely to capture both the exit and entrance sites and therefore have a purely paced ECG complex morphology without fusion.

Reentrant circuits reset with fusion have a higher incidence of flat resetting curves, longer resetting zones, and significantly shorter return cycles measured from the stimulus to the onset of the tachycardia complex. Resetting with fusion is a potential indication that the pacing site is located proximal to the zone of slow conduction (i.e., prior to the entrance site) within the reentrant circuit, whereas resetting without fusion potentially suggests pacing distal to the zone of slow conduction, because pacing closer to the exit is more likely to capture both the exit and entrance sites and produce resetting without fusion.^{37,38}

Resetting of Tachycardias With Diverse Mechanisms

Resetting can be demonstrated for tachycardias based on different mechanisms, including reentry, normal or abnormal automaticity, and triggered activity. Although the ability to reset an arrhythmia is not helpful in distinguishing the underlying mechanism, certain features of the resetting response can be useful for the differential diagnosis.

Site specificity of resetting. Triggered activity and automaticity do not demonstrate site specificity for resetting, whereas reentry can. The closer the stimulus to the entrance site in the reentrant tachycardia circuit, the easier it is to reset the tachycardia. Site specificity for resetting is decreased with the use of multiple extrastimuli.

Resetting response curves. Triggered rhythms secondary to DADs usually have a flat or decreasing resetting curve. A flat resetting curve can be seen in automatic, triggered, or reentrant rhythms. Reentrant rhythms never demonstrate a decreasing resetting curve to single or double extrastimuli.

Resetting with fusion. The ability to reset tachycardia after it has begun activating the myocardium (i.e., resetting with fusion) is diagnostic of reentry and excludes automatic and triggered mechanisms.

eFig. 3.3 Resetting With Fusion. An atrial tachycardia is shown with a stable cycle length (450 milliseconds). A single extrastimulus (*S*) is delivered from the high right atrium (*HRA*) that resets or advances the timing of the next cycle (420 milliseconds); however, the coronary sinus (*CS*) electrogram occurs on time when the extrastimulus is delivered. Thus intracardiac fusion is evident when resetting occurs, signifying macroreentry. *dist*, Distal; *mid*, middle; *prox*, proximal.

In automaticity or triggered activity, resetting of the arrhythmia by an extrastimulus requires depolarization of the site of origin by the paced wavefront. Because the entrance and exit sites of focal rhythms (automatic or triggered) are not separate, a tachycardia wavefront cannot exit the focus once the exit or entrance site has already been depolarized and rendered refractory by the paced wavefront.^{37,38}

During automatic or triggered tachycardias, when an extrastimulus is delivered late in the tachycardia cycle, it can collide with the tachycardia impulse exiting the tachycardia focus and produce fusion of a single beat on the surface ECG or intracardiac recordings. However, in this case, resetting cannot occur because the surrounding myocardium is refractory to the advancing extrastimulus (i.e., entrance block occurs). This produces a fully compensatory pause.

Entrainment of Reentrant Tachycardias

Basic Principles of Entrainment

Entrainment of reentrant tachycardias by external stimuli was originally defined in the clinical setting as “an increase in the rate of a tachycardia to a faster pacing rate, with resumption of the intrinsic rate of the tachycardia upon either abrupt cessation of pacing or slowing of pacing beyond the intrinsic rate of the tachycardia” and taken to indicate an underlying reentrant mechanism. The ability to entrain a tachycardia also establishes that the reentrant circuit contains an excitable gap.^{37,38}

Orthodromic resetting and transient entrainment are manifestations of the same phenomenon (i.e., premature penetration of a tachycardia circuit by a paced wavefront), and the ability to demonstrate resetting is a strong indication that entrainment can occur from that specific pacing site. Entrainment is the continuous resetting of a reentrant circuit by a train of capturing stimuli. However, following the first stimulus of the pacing train that penetrates and resets the reentrant circuit, the subsequent stimuli interact with the reset circuit, which has an abbreviated excitable gap.³⁷

During entrainment, each pacing stimulus creates two activation wavefronts, one in the orthodromic direction and the other in the antidromic direction. The wavefront in the antidromic direction collides with the existing tachycardia wavefront. The wavefront that enters the reentrant circuit in the orthodromic direction (i.e., the same direction as the spontaneous tachycardia wavefront) conducts through the reentrant pathway, resets the tachycardia, and emerges through the exit site to activate the myocardium and collide with the antidromically paced wavefront from the next paced stimulus. This sequence continues until cessation of pacing or block somewhere within the reentrant circuit develops. The first entrained stimulus results in retrograde (antidromic) collision between the stimulated and tachycardia wavefronts, whereas for all subsequent stimuli, the collision occurs between the currently stimulated wavefront and the one stimulated previously. Depending on the degree to which the excitable gap is preexcited (and abbreviated) by the first resetting stimulus, subsequent stimuli fall on fully or partially excitable tissue.^{37,38}

Entrainment is said to be present when two consecutive extrastimuli conduct orthodromically through the circuit with the same conduction time while colliding antidromically with the preceding paced wavefront. Because all pacing impulses enter the tachycardia circuit during the excitable gap, each paced wavefront advances and resets the tachycardia. Thus, when pacing is terminated, the last paced impulse will continue to activate the entire tachycardia reentrant circuit orthodromically at the pacing cycle length (PCL) and also will activate the entire myocardium orthodromically on exiting the reentrant circuit.^{37,38}

Overdrive pacing at long PCLs (approximately 10 to 20 milliseconds shorter than the TCL) can almost always entrain reentrant circuits with large flat resetting curves and a postpacing interval (PPI) equal to the return cycle observed during the flat part of the resetting curve. During

overdrive pacing, once the n th pacing stimulus resets the circuit, the following pacing stimulus ($n + 1$)th will reach the circuit more prematurely. Depending on how premature it is, this ($n + 1$)th extrastimulus may produce no change in the return cycle (compared with that in response to the n th extrastimulus), encounter progressive conduction delay (until a fixed, longer return cycle is reached), or terminate the tachycardia. The larger the flat curve observed during resetting and the longer the PCL, the more likely the return cycle of the n th and ($n + 1$)th extrastimuli will be the same. In this case, no matter how many subsequent extrastimuli are delivered, the return cycle will be the same and equal to that observed during the flat portion of the resetting curve. However, if the flat portion of the resetting curve is small or the PCL is short, the ($n + 1$)th extrastimulus will fall on partially refractory tissue and the return cycle will increase. Continued pacing at the same PCL will result in a stable but longer return cycle than the n th extrastimulus or termination of the tachycardia. Consequently, circuits with large fully excitable gaps (i.e., large flat resetting curves) can demonstrate prolonged return cycles or even termination at PCLs equal to coupling intervals of a single extrastimulus demonstrating a fully excitable gap.

Entrainment Response Curves

During entrainment, the orthodromic wavefront of the last extrastimulus propagates around the circuit to become the first complex of the resumed tachycardia. The conduction time of this impulse to the exit site of the circuit is termed the *last entrained interval*, and it characterizes the properties of the reset circuit during entrainment. Measurement of the interval between the last paced extrastimulus to the first nonpaced tachycardia complex (on the surface ECG or presystolic intracardiac electrogram) during entrainment at progressively shorter PCLs characterizes an entrainment response curve, analogous but not identical to resetting response curves with single extrastimuli. In the setting of entrainment the return cycle depends critically on the number of extrastimuli delivered that reset the circuit before the return cycle is measured because following the first extrastimulus producing resetting (the n th extrastimulus), subsequent extrastimuli are relatively more premature and can lead to a different return cycle.³⁷

During entrainment, the return cycle measured at an orthodromically captured presystolic electrogram should equal the PCL regardless of the site of pacing, as long as the presystolic electrogram is orthodromically activated at a fixed stimulus-to-electrogram interval (i.e., fixed orthodromic conduction time). This would not be observed if the electrogram were captured antidromically. If the time from the orthodromically activated electrogram to the onset of the return cycle on the surface ECG remains constant, which is a requirement to prove that the electrogram is within or attached to the reentrant circuit proximal to the exit site, then the interval from the stimulus to the surface ECG complex will remain constant. The same is true for the electrogram measured at the stimulation site. In the absence of recording of a presystolic electrogram, other measurements may be used to characterize the last entrained interval at any PCL. Therefore, during entrainment, curves relating the PCL to the last entrained interval can be measured from the stimulus to the orthodromic presystolic electrogram, to the onset of the surface ECG of the first tachycardia (nonpaced) complex, or to the local activation time at the pacing site of the first tachycardia (nonpaced) complex. These measurements will be qualitatively identical but have different absolute values. As always, it is important to establish the stability of TCL and document the presence of entrainment before assessing the return cycle and PPI.³⁷

Termination is the usual response to overdrive pacing of circuits that demonstrate an increasing curve in response to resetting by a single extrastimulus. However, if the number of extrastimuli following the n th extrastimulus is limited to one or two (especially at long PCLs),

termination may not occur, although the return cycle will be progressively longer following each extrastimulus. Entrainment is not present until two consecutive PPIs are identical. In such cases, when termination does not occur, the return cycle will be longer than that observed if pacing were discontinued following the *n*th extrastimulus at that PCL. Thus, if only the return cycle following entrainment is used to analyze the excitable gap, an increasing curve suggesting decremental conduction can result, even though a flat curve is observed with single or double extrastimuli. Therefore only resetting phenomena describe the characteristics of the reentrant circuit. Entrainment analyzes a reset circuit that has a shorter excitable gap. Flat, mixed (flat and increasing), and increasing curves can be seen during entrainment of macroreentrant circuits. Increasing curves are almost always observed during entrainment of small or microreentrant circuits.

Relationship of Pacing Site and Cycle Length to Entrainment

As with resetting, entrainment does not require the pacing site be located in the reentrant circuit. However, the closer the pacing site is to the circuit, the less premature a single stimulus can be and reach the circuit and, with pacing trains, the fewer the number of stimuli required before a stimulated wavefront reaches the reentrant circuit without being extinguished by collision with a wave emerging from the circuit.

Overdrive pacing can almost always entrain reentrant tachycardias. However, the number of pacing stimuli required to entrain the reentrant circuit depends on the TCL, the PCL, the duration of the excitable gap of the tachycardia, refractoriness at the pacing site, and the conduction time from the stimulation site to the reentrant circuit.

Diagnostic Criteria of Entrainment

Entrainment is the continuous resetting of a tachycardia circuit. Therefore, during constant rate pacing, entrainment of tachycardia results in the activation of all myocardial tissue responsible for maintaining the tachycardia at the PCL, with the resumption of the intrinsic tachycardia morphology and rate after cessation of pacing. Unfortunately, it is almost impossible to document the acceleration of all tissues responsible for maintaining the reentrant circuit to the PCL. Therefore certain criteria have been proposed for establishing the presence of entrainment: (1) fixed fusion of the paced complexes at a constant PCL; (2) progressive fusion or different degrees of fusion at different PCLs (i.e., the surface ECG and intracardiac morphology progressively look more like the purely paced configuration and less like the pure tachycardia complex in the course of pacing at progressively shorter PCLs); (3) when overdrive pacing at a constant PCL during tachycardia results in tachycardia termination, there is the demonstration of localized conduction block to a site (or sites) for one paced beat associated with interruption of the tachycardia, followed by activation of that site (or sites) by the next paced P wave from a different direction and with a shorter conduction time; and (4) during overdrive pacing at two different rates during tachycardia, there is change in conduction time to and electrogram morphology at the electrode recording site.³⁷⁻³⁹ These criteria are discussed in more detail in **Chapter 5**.

Mechanism of Slow Conduction in the Reentrant Circuit

As mentioned earlier, a condition necessary for reentry is that the impulse be delayed sufficiently in the alternative pathway or pathways to allow tissues proximal to the site of unidirectional block to recover excitability. All types of reentrant arrhythmias have a basic feature in common—the wavefront must encounter a zone of tissue where local electrical inhomogeneity is present. This inhomogeneity can be related to electrical properties of the individual cardiac myocyte that generates the action potential (inhomogeneity in electrical excitability or refractoriness), passive properties governing the flow of current among cardiac cells

(cell-to-cell coupling and tissue geometry), or combinations of those conditions. Such changes can be permanent (e.g., in remodeling after ventricular hypertrophy or infarction), or they can be purely functional (e.g., inhomogeneity of refractoriness in acutely ischemic tissue). In addition, some of those changes are needed only to set the initial condition for the deviation of the impulse, the so-called unidirectional conduction block. Once the disturbance is initiated, an arrhythmia can develop in a perfectly homogeneous electrical medium.

Slow conduction within the reentrant circuit is also an important determinant of the size of the reentrant circuit. A decrease in conduction velocity results in a reduction in the wavelength and a lessening of the amount of tissue needed to sustain reentry. In contrast, an increase in conduction velocity prolongs the wavelength of excitation, and hence a larger anatomical circuit is necessary to sustain reentry. If a larger circuit is not possible, initiation or maintenance of tachycardia cannot occur.

In some cardiac tissues (e.g., the AVN), slow conduction is normal physiology. Slow conduction also can be secondary to pathophysiological settings (e.g., MI) or caused by functional properties that can develop as a result of premature stimulation or evolve during a rapid transitional rhythm.

As discussed in **Chapter 1**, action potential propagation and conduction velocity in cardiac tissue are determined by source-sink relationships, which reflect the interplay between the active membrane properties of cardiac cells (the source generating the action potential) and the passive properties determined by architectural features of the myocardium (sink), as well as the coupling resistance between source and sink. The current provided by the source must reach the sink. The pathway between the source and sink includes intracellular resistance (provided by the cytoplasm) and intercellular resistance (provided by the gap junctions). Extracellular resistance plays a role, but it can often be neglected. The coupling resistance is mainly determined by resistance of the gap junctions. Therefore the number and distribution of gap junctions, as well as the conductance of the gap junction proteins (connexins), are important factors for conduction of the action potential.

The safety factor for conduction predicts the success of action potential propagation and is defined as the ratio of the current generated by the depolarizing ion channels of a cell (source) to the current consumed during the excitation cycle of a single cell in the tissue (sink). Thus the safety factor for propagation is proportional to the excess of source current over the sink needs. By this definition, conduction fails when the safety factor drops to less than 1 and becomes increasingly stable as it rises to more than 1. This concept of propagation safety provides information about the dependence of propagation velocity on the state of the ion channels, cell-to-cell coupling, and tissue geometry. In essence, local source-sink relationships determine the formation of conduction heterogeneities and provide conditions for the development of slow conduction, unidirectional block, and reentry.

Reduced Membrane Excitability

Excitability of a cardiac cell describes the ease with which the cell responds to a stimulus with a regenerative action potential, and it depends on the passive and active properties of the cell membrane. The passive properties include the membrane resistance and capacitance and the intercellular resistance. The most important determinant of reduced excitability is the reduced availability of Na⁺ channels. The more negative the membrane potential is, the more Na⁺ channels are available for activation, the greater the influx of Na⁺ into the cell during phase 0, and the greater the conduction velocity. In contrast, membrane depolarization to levels of −60 to −70 mV can inactivate half the Na⁺ channels, and depolarization to −50 mV or less can inactivate all the Na⁺ channels.

Reduced membrane excitability occurs in numerous physiological and pathophysiological conditions. When stimulation occurs during phase 3 (e.g., premature stimulation during the relative refractory period), before full recovery and at less negative potentials of the cell membrane, a portion of Na^+ channels will still be refractory and unavailable for activation (due to prolonged recovery of Na^+ channels from inactivation). As a result, I_{Na} and phase 0 of the next action potential are reduced, and conduction of the premature stimulus is slowed, facilitating reentry. Reduced membrane excitability is also present in cardiac cells with persistently low levels of resting potential caused by disease (e.g., acute ischemia, certain electrical remodeling processes), genetic mutations that result in loss of Na^+ channel function (e.g., Brugada syndrome), tachycardia, and treatment with class I antiarrhythmic agents.¹⁹

Action potentials with reduced upstroke velocity resulting from partial inactivation of Na^+ channels are called “depressed fast responses.” These action potential changes are likely to be heterogeneous, with unequal degrees of Na^+ inactivation that create areas with minimally reduced velocity, more severely depressed zones, and areas of complete block. In addition, refractoriness in cells with reduced membrane potentials can outlast voltage recovery of the action potential; that is, the cell can still be refractory or partially refractory after the E_m returns to its most negative value. With progressive reduction of excitability, less Na^+ source current is generated, and conduction velocity and the safety factor decrease monotonically. When the safety factor falls to less than 1, conduction can no longer be sustained, and failure (conduction block) occurs.

Thus, in a diseased region with partially depolarized fibers, there can be some areas of slow conduction and some areas of conduction block, depending on the level of resting potential and the number of Na^+ channels that are inactivated. This combination can create a substrate for reentry. The chance for reentry in such fibers is even greater during premature activation or during rhythms at a rapid rate, because slow conduction or the possibility of block is increased even further.

Notably, reduced membrane excitability does not support very slow conduction; rather, it leads to a transition to abrupt conduction failure from conduction velocities that are relatively fast (Fig. 3.16). The safety factor decreases very slowly and is relatively insensitive to moderate changes in membrane excitability. Only when there is extreme (90%) reduction in Na^+ channel availability, the generated depolarizing charge is not sufficient to depolarize the membrane to excitation threshold, and the safety factor drops precipitously toward 1 (in a nonlinear “all-or-none” behavior of the cell membrane and the threshold phenomenon that characterizes the excitation process).

Reduced Cellular Coupling

Intercellular communication is maintained by gap junctional channels that connect neighboring cells and allow biochemical and low-resistance electrical coupling. Although the resistivity of the gap junctional membrane for the passage of ions and small molecules and for electrical propagation is several orders of magnitude higher than the cytoplasmic intracellular resistivity, gap junction coupling provides a resistance pathway that is several orders of magnitude lower compared with uncoupled cell membranes.

In normal adult working myocardium, a given cardiomyocyte is electrically coupled to an average of approximately 11 adjacent cells, with gap junctions being predominantly localized at the intercalated discs at the ends of the rod-shaped cells. Lateral (side-to-side) gap junctions in nondisc lateral membranes of cardiomyocytes are much less abundant and occur more often in atrial than ventricular tissues. This particular subcellular distribution of gap junctions is a main determinant of anisotropic conduction in the heart; a wavefront must traverse more cells in the transverse direction than over an equivalent distance

Fig. 3.16 Computer Simulation of the Effects of a Gradual Reduction of Membrane Excitability on the Characteristics of Impulse Propagation. (A) Dependence of conduction velocity and of the safety factor for conduction on membrane excitability. Conduction velocity (solid line) and safety factor of conduction (dashed line) versus Na^+ channel availability (% \bar{g}_{Na}). Both velocity and safety factor decrease monotonically as membrane excitability is reduced. Horizontal bars indicate conduction failure, which occurs when the safety factor decreases to less than 1. (B) Dependence of maximal upstroke velocity and maximal sodium inward current on membrane excitability. (From Rohr S. Role of gap junctions in the propagation of the cardiac action potential. *Cardiovasc Res*. 2004;62: 309–322.)

in the longitudinal direction because cell diameter is much smaller than cell length. In addition, with less intercellular gap junctional coupling, greater resistance and slower conduction occurs transversely than longitudinally.¹⁹

Modification of intercellular coupling occurs in numerous physiological and pathophysiological conditions. Physiologically, cell-to-cell coupling is reduced in atrial and ventricular myocardium in the transverse direction to the main fiber axis relative to the longitudinal direction. Reduced intercellular coupling also likely contributes to slow impulse conduction in the AVN. In pathophysiological settings (e.g., myocardial ischemia, ventricular hypertrophy, cardiomyopathy), modification of intercellular coupling can occur as a consequence of acute changes in the average conductance of gap junctions secondary to ischemia, hypoxia, acidosis, or increase in intracellular Ca^{2+} , or it can be produced by changes in expression or cellular distribution patterns of gap junctions. Changes in the distribution and number of gap junctions (gap junction remodeling) have been reported in almost all cardiac diseases predisposing to arrhythmias. Remodeling includes a decrease in some gap junction channels resulting from the interruption of communication between cells by fibrosis and downregulation of connexin 43 (Cx43)

formation or trafficking to the intercalated disc. In addition, gap junctions can become more prominent along lateral membranes of myocytes (so-called structural remodeling).⁴⁰

Similar to its behavior during reduced membrane excitability, conduction velocity decreases monotonically with reduction in intercellular coupling. However, partial gap junctional uncoupling was shown to result in conduction velocities that are over an order of magnitude slower than those obtained during a maximal reduction of excitability.¹⁹ In fact, very slow electrical propagation, necessary to explain very small local reentry circuits, cannot occur with reduced membrane excitability alone, and it necessitates the presence of either very low levels of intercellular coupling or highly discontinuous architecture of the myocytes network.⁴¹

Importantly, the changes in the safety factor resulting from intercellular uncoupling are opposite to those observed with reduction in membrane excitability (Fig. 3.17). The safety factor increases to a maximum as coupling is reduced and velocity is significantly slowed. Electrical coupling between adjacent cells is an important determinant of source-sink balance. As cells become less coupled, there is greater confinement of depolarizing current to the depolarizing “source” cell, with less electrotonic load and axial flow of charge to the downstream “sink” cells (the source is less likely to become overwhelmed by the demand from neighboring cells). As a result, individual cells depolarize with a high margin of safety, but conduction proceeds with long intercellular delays. At such low levels of coupling, conduction is very slow but paradoxically very robust. Due to the high safety factor, extremely slow conduction velocities can be sustained in tissue with greatly reduced intercellular coupling. Only at extreme levels of uncoupling do propagation block occur.^{30,40,42,43}

Importantly, there is a high redundancy in connexin expression in the heart with regard to conduction of electrical impulse, and a large reduction of intercellular coupling is required to cause major slowing of conduction velocity. It has been shown that a 50% reduction in Cx43 does not alter ventricular impulse conduction. Cx43 expression must

decrease by 90% to affect conduction, but even then conduction velocity is reduced only by 20%.⁴⁰

Tissue Structure and Geometry

Tissue geometry can influence action potential propagation and conduction velocity. In contrast to an uncoupled cell strand, in which the high resistance junctions alternate with the low cytoplasmic resistance of the cells, a high degree of discontinuity can be produced by large tissue segments (consisting of a segment with side branches) alternating with small tissue segments having a small tissue mass (connecting segments without branches).¹⁹

When a small mass of cells has to excite the large mass (the so-called tissue expansion), transient slowing of the conduction velocity can be observed at the junction. This occurs, for instance, with an impulse passing abruptly from a narrow bundle of myocardial fibers into a large tissue layer or propagating into a region where there is an abrupt increase in branching of the myocardium). In this setting, conduction slowing or block can occur because of sink-source mismatch; the current provided by the excitation wavefront (current source) is insufficient to charge the capacity and thus excite the much larger volume of tissue ahead (current sink).^{19,41,44}

In a normal heart, abrupt changes in geometric properties are not of magnitude to provide sufficient sink-source mismatch and cause conduction block of the normal action potential because the safety factor for conduction is large; that is, there is a large excess of activating current over the amount required for propagation. However, when the action potential is abnormal, the unexcited area has reduced excitability (e.g., in the setting of acute ischemia), or both, anatomical impediments can result in conduction block.

Furthermore, the fibrosis that accompanies aging, heart disease, and heart failure increases the extent and heterogeneity of structural discontinuity. Fibrotic myocardium exhibits slow, inhomogeneous, and strongly anisotropic conduction, likely secondary to reduced intercellular coupling, discontinuous branching architecture, and zigzagging circuits. Fibrotic strands typically occur between the cardiomyocytes, running parallel to their longitudinal axis, thus separating laterally neighbored cardiomyocytes, with reduced transverse conduction velocity. Fibroblasts, although nonexcitable, may allow electrotonic spread of activation, but with considerable delay. Of note, experimental studies suggest that fibroblasts might couple via gap junctions to cardiomyocytes; however, it remains unclear whether fibroblast-myocyte coupling occurs *in vivo*.⁴⁵

Anisotropy and Reentry

The anisotropic cellular structure of the myocardium is important for the understanding of normal propagation and arrhythmogenesis. Structural anisotropy can relate to cell shape and to the cellular distribution pattern of proteins involved in impulse conduction, such as gap junction connexins and membrane ion channels. The anisotropic architecture of most myocardial regions, consisting of elongated cells forming strands and layers of tissue, leads to a dependence of propagation velocity on the direction of impulse spread.¹⁹ In normal ventricular myocardium, conduction in the direction parallel to the long axis of the myocardial fiber bundles is approximately 3 to 5 times more rapid than that in the transverse direction. This is attributable principally to the lower resistivity of myocardium in the longitudinal versus the transverse direction; hence intercellular current flow occurs primarily at the cell termini (although propagation also occurs transversely). As discussed previously, the gap junctions of the intercalated discs form a major source of intercellular resistance to current flow between fiber bundles. Therefore the structure of the myocardium that governs the extent and distribution of these gap junctions has a profound influence on axial resistance and conduction.

Fig. 3.17 Computer Simulation of the Effects of a Gradual Reduction of Gap Junctional Coupling on the Characteristics of Impulse Propagation. Conduction velocity (solid line) and safety factor for conduction (dashed line) versus gap junction conductance. Velocity decreases monotonically as coupling is reduced. In contrast, the safety factor first “paradoxically” increases to a maximum and then decreases sharply to the point of conduction block (horizontal bar at safety factor of 1). (From Rohr, S. Role of gap junctions in the propagation of the cardiac action potential. *Cardiovasc Res.* 2004;62:309–322.)

Cellular Coupling: Gap Junctional Organization

The anisotropic conductive properties of ventricular myocardium are dependent on the geometry of the interconnected cells and the number, size, and location of gap junction channels between them. In addition, gap junctions vary in their molecular composition, degree of expression, and distribution pattern, whereby each of these variations can contribute to the specific propagation properties of a given tissue. Tissue-specific connexin expression and gap junction spatial distribution, as well as the variation in the structural composition of gap junction channels, allow for a greater versatility of gap junction physiological features and enable disparate conduction properties in cardiac tissue.⁴⁰

Three different connexins are prominently expressed in the atrial and ventricular myocardium: Cx40, Cx43, and Cx45, named for their molecular masses. A fourth connexin has been described in the AVN (Cx31.9). Cx40 gap junction channels exhibit the largest conductance and Cx45 the smallest. The myocytes of the sinus node and AVN are equipped with small, sparse, dispersed gap junctions containing Cx45, a connexin that forms low conductance channels, thus underlying the relatively poor intercellular coupling in nodal tissues, a property that is linked to slowing of conduction. In contrast, atrial myocardium gap junctions consist mainly of Cx43 and Cx40, ventricular myocardium of Cx43, and the and Purkinje fibers of Cx40.⁴⁰

Alterations in distribution and function of cardiac gap junctions are associated with conduction delay or block. Inactivation of gap junctions decreases transverse conduction velocity to a greater degree than longitudinal conduction, thereby resulting in exaggeration of anisotropy and providing a substrate for reentrant activity and increased susceptibility to arrhythmias.

Myocyte Packing and Tissue Geometry

Discontinuities in myocardial architecture exist at several levels. In addition to discontinuities imposed by cell borders, microvessels and connective tissue sheets separating bundles of excitable myocytes can act as resistive barriers. A propagating impulse is expected to collide with such barriers and travel around them wherever it encounters excitable tissue.

In some regions of the myocardium (e.g., the papillary muscles), connective tissue septa subdivide the myocardium into unit bundles, each composed of 2 to 30 cells surrounded by a connective tissue sheath. Within a unit bundle, cells are tightly connected or coupled to each other longitudinally and transversely through intercalated discs that contain the gap junctions and are activated uniformly and synchronously as an impulse propagates along the bundle. Adjacent unit bundles also are connected to each other. Unit bundles are coupled better in the direction of the long axis of its cells and bundles (because of the high frequency of the gap junctions within a unit bundle) than in the direction transverse to the long axis (because of the low frequency of interconnections between the unit bundle). This is reflected as a lower axial resistivity in the longitudinal direction than in the transverse direction in cardiac tissues composed of many unit bundles. In addition, anisotropy on a macroscopic scale can influence conduction at sites at which a bundle of cardiac fibers branches or separate bundles will coalesce. Marked slowing can occur when there is a sudden change in the fiber direction, causing an abrupt increase in the effective axial resistivity. Conduction block, which sometimes can be unidirectional, can occur at such junction sites, particularly when membrane excitability is reduced.

Uniform Versus Nonuniform Anisotropy

Uniform anisotropy is characterized by smooth wavefront propagation in all directions, and measured conduction velocity changes monotonically on moving from fast (longitudinal) to slow (transverse) axes, thus indicating relatively tight coupling between groups of fibers in all direc-

tions. However, this definition is based on the characteristics of activation at a macroscopic level, where the spatial resolution encompasses numerous myocardial cells and bundles, and therefore it describes the behavior of the myocardial syncytium. In contrast, when the three-dimensional network of cells is broken down into linear single-cell chains, gap junctions can be shown to limit axial current flow and induce saltatory conduction because of the recurrent increases in axial resistance at the sites of gap junctional coupling; that is, conduction is composed of rapid excitation of individual cells followed by a transjunctional conduction delay. In two- and three-dimensional tissue, these discontinuities disappear because of lateral gap junctional coupling, which serves to average local small differences in activation times of individual cardiomyocytes at the excitation wavefront.⁴⁴

In multicellular tissue, saltatory conduction reappears only under conditions of critical gap junctional uncoupling, which leads to a functional unmasking of the cellular structure and induces ultraslow and meandering conduction, well known to be a key ingredient in arrhythmogenesis. Change in the characteristics of anisotropic propagation at the macroscopic scale from uniform to nonuniform strongly predisposes to reentrant arrhythmias. Nonuniform anisotropy has been defined as tight electrical coupling between cells in the longitudinal direction but uncoupling to the lateral gap junctional connections. Therefore there is disruption of the smooth transverse pattern of conduction characteristic of uniform anisotropy, which results in a markedly irregular sequence or zigzag conduction, producing the fractionated extracellular electrograms characteristic of nonuniform anisotropic conduction (Fig. 3.18). In nonuniformly anisotropic muscle, there also can be an abrupt transition in conduction velocity from the fast longitudinal direction to the slow transverse direction, unlike the case with uniform anisotropic muscle, in which intermediate velocities occur between the two directions.³⁰

Nonuniform anisotropic properties can exist in normal cardiac tissues secondary to separation of the fascicles of muscle bundles in the transverse direction by fibrous tissue that proliferates with aging to form

Fig. 3.18 Effect of Scar on Electrical Propagation. (A) A homogeneous sheet of myocardium conducts an electrical wavefront rapidly, with synchronous activation of a large number of cells that leads to a sharp electrogram. (B) Myocardial scarring produces disordered propagation, resulting in a low-amplitude electrogram, with multiple fragmented peaks.

longitudinally oriented insulating boundaries (e.g., crista terminalis, interatrial band in adult atria, or ventricular papillary muscle). Similar connective tissue septa cause nonuniform anisotropy in pathological situations such as chronic ischemia or a healing MI, in which fibrosis in the myocardium occurs (see Fig. 3.18).⁴⁶

Mechanism of Unidirectional Block in the Reentrant Circuit

Unidirectional block occurs when an impulse cannot conduct in one direction along a bundle of cardiac fibers but can conduct in the opposite direction. As mentioned earlier, this condition is necessary for the occurrence of classic reentrant rhythms. Several mechanisms, involving active and passive electrical properties of cardiac cells, can cause unidirectional block. Expression of ion channels and associated flow of depolarizing currents (I_{Na} and I_{CaL}), cell-to-cell electrical coupling, and microscopic tissue structure all interact to define local propagation and risk of unidirectional propagation block in tissues with a discontinuous structure such as occurs in the heart.⁴⁰

Inhomogeneity of Membrane Excitability and Refractoriness

Unidirectional block develops when the activation wavefront interacts with the repolarization phase (tail) of a preceding excitation wave. There is a critical or vulnerable window during the relative refractory period of a propagating action potential within which unidirectional block occurs (Fig. 3.19). When a premature stimulus is delivered outside this window, the induced action potential propagates or blocks in both directions; specifically, a stimulus delivered too early fails to induce a propagating action potential in either direction (bidirectional block), whereas a late stimulus results in bidirectional conduction (no block). In contrast, when a stimulus is applied within the vulnerable window,

the induced action potential propagates incrementally in the retrograde direction because the tissue is progressively more recovered as the distance from the window increases in this direction, but it blocks in the anterograde direction following a short distance of decremental conduction because the tissue is progressively less excitable as the distance from the window increases in this direction.¹⁹

The size of the vulnerable window provides an index of the vulnerability to the development of reentrant arrhythmias. Therefore the probability that a premature stimulus will fall inside the window and induce reentry is high when the vulnerable window is large. In contrast, precise timing of a premature stimulus is required to induce reentry in a small window, and the probability of such an event is low. In normal tissue the vulnerable window is very small and inducibility of unidirectional block and reentry is negligible. The width of the vulnerable window can be affected by changes in the availability of Na^+ channels for depolarization, cell-to-cell coupling, and repolarizing I_K . In addition, the size of the vulnerable window can be widened (and reentry facilitated) by factors that increase the spatial inhomogeneity of refractoriness or decrease cellular coupling via gap junctions.

Unidirectional conduction block in a reentrant circuit also can be persistent and independent of premature activation, in which case it often occurs in a region of depressed and heterogeneous excitability (as occurs in acute ischemia); this leads to a widening of the vulnerable window. Asymmetry in excitability, which can occur because of asymmetrical distribution of a pathological event, can lead to an abrupt rise in the threshold for excitation in one direction and to a more gradual rise in the other. Conduction fails when the wavefront encounters the least depressed site first and is successful in the direction in which it encounters the most depressed site first. In addition, impulses are conducted more easily from a rapidly conducting tissue to a slowly conducting tissue than in the opposite direction.⁴⁷

Local dispersion of refractory periods is a normal feature of ventricular myocardium. Critical increases in the dispersion of refractoriness (i.e., the difference between the shortest and longest refractory periods) can result in the local widening of the vulnerability window and an increased probability for the generation of unidirectional block and reentry. Increased heterogeneity of repolarization and dispersion of refractoriness can be caused by acute or prolonged ischemia, the LQTS, or electrical remodeling in the setting of ventricular hypertrophy and failure, and in the setting of MI. When differences in the duration of the refractory periods occur in adjacent areas, conduction of an appropriately timed premature impulse can be blocked in the region with the longest refractory period, which then becomes a site of unidirectional block, whereas conduction continues through regions with a shorter refractory period.

Anisotropy and Unidirectional Block

The anisotropic properties of cardiac muscle can contribute to the occurrence of unidirectional block. As mentioned earlier, in the anisotropic muscle, the safety factor for conduction is lower in the longitudinal direction of rapid conduction than in the transverse direction of slow conduction. The low safety factor longitudinally is a result of a large current load on the membrane associated with the low axial resistivity and a large membrane capacitance in the longitudinal direction. This low safety factor can result in a preferential conduction block of premature impulses in the longitudinal direction while conduction in the transverse direction continues. The site of block in the longitudinal direction can become a site of unidirectional block that leads to reentry. In contrast to the propensity of premature impulses to block in the longitudinal direction in nonuniformly anisotropic myocardium because of the decreased depolarizing current and low safety factor, when coupling resistance between cells is increased, conduction of all impulses

Fig. 3.19 Schematic Representation of the Vulnerable Window During the Refractory Period of a Propagating Action Potential. The critical or vulnerable window within which unidirectional block occurs can be characterized as a time interval or window (TW), or alternatively, it can be represented as a distance in the space domain (SW) or as a range of membrane potentials in the voltage domain (VW). (From Kléber AG, Rudy Y. Basic mechanisms of cardiac impulse propagation and associated arrhythmias. *Physiol Rev.* 2004;84:431–488.)

will block first in the transverse direction. Preferential block in this direction occurs because an increase in coupling resistance will reduce the safety factor to less than the critical level needed to maintain transverse conduction before the safety factor for longitudinal conduction is reduced to this critical level.

Discontinuities in Tissue Structure and Geometry

Geometric factors related to tissue architecture also can influence impulse conduction and, under certain conditions, lead to unidirectional block. Structural discontinuities exist in the normal heart in the form of trabeculations of the atrial and ventricular walls, sheets interconnected by small trabeculae, or myocardial fibers with different diameters packed in a connective tissue matrix. Structural discontinuities can also be secondary to pathophysiological settings, such as the connective tissue septa characteristic of aging, infarcted, hypertrophic, and failing myocardium. The propagating excitation wave is expected to interact with these normal and abnormal structural discontinuities. These structural features influence conduction by affecting the axial currents that flow ahead of the propagating wavefront.⁴⁷ Therefore an impulse conducting in one direction can encounter a different sequence of changes in fiber diameter, branching, and frequency and distribution of gap junctions than it does when traveling in the opposite direction. The configuration of pathways in each direction is not the same.⁴⁶

Such tissue structures can exhibit directional asymmetry in source-sink relationships. Depending on the size of the source-sink mismatch, this results in either local conduction delays or conduction blocks at the junction during anterograde conduction, where the source is smaller than the sink. On the other hand, conduction remains preserved in the opposite direction, where the source is larger than the sink. As a consequence, unidirectional block develops. Similar phenomena occur at other types of structural discontinuities such as pivot points and isthmuses.^{28,42,43,48}

Importantly, discontinuities in propagation are very sensitive to the state of underlying electrical cell-to-cell coupling. Although a reduction of gap junctional conductance (e.g., during ischemia) can promote arrhythmogenesis by slowing conduction velocities, partial gap junctional uncoupling has the capacity to remove unidirectional conduction blocks and therefore act, at least over a certain range of partial uncoupling, in an antiarrhythmogenic fashion. Partial uncoupling of cells at the junction of source-sink mismatch decrease in the current sink and hence reduces dissipation of local (source) current. Reduced dispersion of the source current protects the impulse from being blocked at the point of abrupt expansion of cardiac tissue. As a consequence, partial cell-to-cell uncoupling can reverse the unidirectional block and allow bidirectional propagation.

INDICATIONS

Invasive electrophysiological (EP) testing involves recording a portion of cardiac electrical activity and programmed cardiac electrical stimulation via multipolar catheter electrodes positioned percutaneously strategically at various locations within the cardiac chambers. EP testing is used predominantly in patients with suspected or documented cardiac arrhythmias when the precise EP diagnosis is required for management decisions or when catheter ablation is planned. In addition, EP testing is of value in selected groups of patients for risk stratification of life-threatening arrhythmias. The role of EP testing in specific cardiac electrical and structural cardiac diseases is discussed in subsequent chapters.

PERIPROCEDURAL MANAGEMENT

Preprocedure Evaluation

Heart failure, myocardial ischemia, and electrolyte abnormalities should be treated and adequately controlled before any invasive EP testing is

undertaken. Patients with critical aortic stenosis, severe hypertrophic cardiomyopathy, left main or severe three-vessel coronary artery disease, or decompensated heart failure are at higher than average risk of complications. Induction of sustained tachyarrhythmias in these patients can cause rapid and severe hemodynamic deterioration. In addition, assessment of the risks for sedation and anesthesia must be performed prior to the procedure.

Consent

Patients generally are not as familiar with EP procedures as they are with other invasive cardiac procedures such as coronary angiography. Therefore patient education is an essential part of the procedure, and is best delivered in the outpatient setting before the procedure day. The patient should be informed about the value of the EP study, its risks, and the expected outcome. Patients should also have a realistic idea of the benefit that they can derive from undergoing EP studies, including the possibility that the study result can yield negative or equivocal results.¹

Obtaining an informed consent is an integral part of the procedure and is not only a legal requirement but also an ethical obligation. The discussion should take place out of the procedure room and be in a language that the patient adequately understands. Common risks, even if not considered serious, should be discussed, as should serious risks that are potentially life threatening, even if exceedingly rare. All aspects of the procedure that can be reasonably anticipated should be included in the discussion. Patients should be given ample opportunity to discuss their concerns about the procedure and to have their questions answered satisfactorily.¹

Procedural Sedation

Some degree of sedation is required in most patients undergoing invasive EP procedures to relieve anxiety, discomfort, and pain. Also, sedation is often necessary to prevent patient movements during long and potentially painful procedures. Patient movement can expose the patient to potential risk during transseptal puncture, pericardial access, or catheter dislocation during ablation in close proximity to critical structures. In addition, large shifts in reconstructed geometry on the electroanatomical map resulting from patient movement can hinder mapping and ablation efforts.^{2,3}

Sedation and anesthetic practices vary dramatically among different institution and operators. There is variation in the selection of patients for sedation or general anesthesia, the personnel administering sedation, the agents employed, and the technique for monitoring sedation.¹

Several patient factors warrant consultation with an anesthesiologist, such as increased risk for airway obstruction or difficult mask ventilation (e.g., obesity, obstructive sleep apnea, anatomical factors) and high risk for sedation complications (e.g., pulmonary disease, heart failure, hemodynamic instability, psychiatric or neuromuscular disorders, previous problems with anesthesia or sedation, and medication or substance use that complicates the administration of sedative agents, such as chronic opioid or benzodiazepine use, alcohol abuse).⁴

Types of Anesthesia

The anesthetic plan must be individually tailored, depending on the nature of procedure, patient characteristics, hospital resources, patient preference, and anesthesia skill/training of the EP team. Furthermore, changes in the level of sedation and in the type of drugs used can be necessary during the course of the procedure and must be aligned with the needs of the interventional procedures. For example, the optimal degree of anesthesia may vary from minimal (during induction of arrhythmias) to deep (during painful ablation or electrical cardioversion). Also, the anesthesiologist should be asked to avoid or minimize nondepolarizing muscle relaxants when the evaluation of phrenic nerve function is required during ablation. Therefore close communication and collaboration between the electrophysiologists and anesthesia providers are crucial to perform EP procedures safely and successfully.^{5,6}

One of following anesthesia techniques or their combinations may be used: (1) local anesthesia at the site of vascular access; (2) conscious (moderate) sedation with intravenous (IV) sedatives; (3) deep sedation with IV sedatives; and (4) general anesthesia.²

Local anesthesia. Infiltration of the site of vascular access with local anesthetics is commonly used. Lidocaine is the local anesthetic of choice given its fast onset of action and safety profile. Bupivacaine offers longer periods of analgesia after procedure completion, but it is not preferred due to its cardiac toxicity. Local anesthesia may be preferred to IV sedation when arrhythmia induction is expected to be adversely affected by sedation (e.g., automatic or triggered-activity tachycardias). This approach requires a well-informed and cooperative patient who can cope with lying still during the procedure.² Of note, injecting large

amounts of lidocaine can result in systemic levels that might affect arrhythmia induction.

Conscious sedation. Mild to moderate conscious sedation, in conjunction with local anesthesia, is utilized in most EP procedures. The combination of a benzodiazepine and a narcotic are typically used to provide analgesia, sedation, and amnesia. Midazolam and fentanyl are preferred because of their rapid onset, titratability, reversibility, and very wide therapeutic window.²

It is important to recognize that sedation and general anesthesia are part of a continuum, and there is a danger of patients unintentionally slipping into anesthesia with the loss of spontaneous ventilation, requiring immediate airway intervention. The transition from moderate to deeper levels of sedation can occur suddenly and unexpectedly. In fact, oversedation, loss of airway, necessity of airway intervention, or conversion to general anesthesia is reported to occur in 40% of non-general anesthesia EP procedures. Therefore even when mild to moderate levels of sedation are targeted with only benzodiazepine and narcotics, the electrophysiologist and EP staff performing the procedure must be knowledgeable and trained to promptly recognize and treat sedation-related adverse events in the absence of a specialist anesthesiologist. Hence, some operators prefer to have anesthesia providers (anesthesiologists or nurse anesthetists working with anesthesiologists) provide monitored anesthesia care (MAC) during such procedures, especially given the fact that an unplanned need for deep sedation (e.g., for electrical cardioversion of induced atrial fibrillation [AF] or ventricular tachycardia [VT]) or unpredicted complications (e.g., cardiac perforation, worsening heart failure) not infrequently arise during the course of the procedure. The latter approach allows the electrophysiologist to focus solely on the technical aspects of the procedure and share the responsibility for the patient with the anesthesia care team. The decision to involve an anesthesiologist ideally should be made before the start of the procedure. The practice of calling the anesthesia team only as needed during the course of the procedure to provide deeper levels of sedation or to rescue a deteriorating patient or manage airway emergencies is suboptimal for patient care and is not recommended.^{3,7,8}

Deep sedation. Deep levels of sedation can be required for longer procedures, such as for AF or VT ablation, and during electrical cardioversion. Deep sedation is administered under the supervision of an anesthesiologist. Although the combination of midazolam and fentanyl is commonly utilized, the use of propofol for cardiac procedures has recently been reported in several large series. Propofol has rapid onset and offset of action and an excellent safety profile; however, it also has profound respiratory depressant actions as well as vasodilatory and myocardial depressant effects, which can cause hypotension, particularly when used with other anesthetics. Propofol offers significant advantages over benzodiazepines, including more rapid induction, better acute intraprocedural control of sedation level, and more rapid recovery. Continuous infusions of IV sedatives are preferred to repeated boluses to avoid waxing and waning levels of consciousness.^{7,9}

Other options include a low dose of ketamine or etomidate. Ketamine has minimal respiratory and stimulatory effects on blood pressure and heart rate, a significant advantage in patients with preexisting hypotension or bradycardia. Etomidate also has a stable hemodynamic profile but a high incidence of transient myoclonus and nausea.^{2,10}

When deep sedation is required for only a brief period (e.g., for direct current cardioversion), IV anesthetics (such as methohexital, propofol, or etomidate) may be considered.²

General anesthesia. General anesthesia has increasingly been used for complex EP procedures. Advantages of general anesthesia include optimal airway management, pain control, and patient immobilization, as well as enhanced tolerance of esophageal temperature probes. However, this requires the additional expense and time of a dedicated anesthetic

team in the laboratory, and turn around between patients is prolonged by induction of anesthesia and recovery. In addition, the use of general anesthesia is associated with an increased risk of trauma during intubation and esophageal complications, as well as the delay in recognition of and intervention for thromboembolic complications.⁴ Furthermore, general anesthetics can suppress inducibility of various arrhythmias or render them hemodynamically unstable by the abolition of sympathetic tone for compensatory vasoconstriction.^{5,11}

Propofol or etomidate is commonly used for induction. Midazolam is often administered to patients upon arrival in EP laboratory for its anxiolytic and amnesic effects. Rocuronium is a preferred muscle relaxant to facilitate the intubation. Anesthesia is usually maintained by an inhalation agent (nitrous oxide, isoflurane, sevoflurane, or desflurane), combined with IV narcotics.² Importantly, if there is concern about phrenic nerve stimulation or injury, the anesthesiologist should be asked to avoid or minimize nondepolarizing muscle relaxants to verify the preservation of diaphragmatic function.¹²

Jet Ventilation

Using high-frequency ventilation during general anesthesia decreases the regular chest wall motion associated with standard mechanical ventilation, thus minimizing respiration-related cardiac movement. Recent data suggest that the use of jet ventilation in the EP laboratory can enhance catheter stability during mapping and ablation and potentially improve the efficacy and safety of the ablation procedure, especially when a stable field needs to be established.^{1,8}

On the other hand, several disadvantages of high-frequency jet ventilation have been reported, including the lack of airtight sealing of airway to decrease secretions, the inability to use inhaled anesthesia, and the difficult measurement of resulting ventilator parameters and efficiency of gas exchange. Furthermore, the risk of barotrauma (e.g., volutrauma, pneumothorax, mediastinal emphysema) is increased, especially in patients with chronic obstructive pulmonary disease. Mucosal damage, especially necrotizing tracheobronchitis, has been reported, and can be prevented by adequate humidification of the ventilator circuit.³

Electrophysiological Effects of Anesthetic Medications

The exact influences anesthetics have on cardiac EP in the clinical setting are not entirely certain. In general, sedation of any kind decreases endogenous catecholamine release, potentially suppressing arrhythmic activity, which can impede the mapping and ablation procedure. Nonetheless, some anesthetics (e.g., ketamine) induce sympathetic stimulation, which can potentially facilitate or induce arrhythmias.

Benzodiazepines reduce blood pressure by decreasing peripheral vascular resistance leading to reflex tachycardia. Opioids, especially at high doses, have a central vagotonic effect with resultant bradycardia. Propofol can trigger vagally mediated bradycardia and inhibit spontaneous ventricular arrhythmias.

Inhalational anesthetics enhance automaticity of latent atrial pacemakers relative to the sinus node, promoting ectopic atrial rhythms and wandering atrial pacemakers. In addition, these agents demonstrate varying effects on the atrioventricular node (AVN) and His-Purkinje system (HPS). Isoflurane prolongs the atrial refractory period and delays ventricular repolarization, but the clinical significance of these effects appears minimal.

Neuromuscular relaxants modulate autonomic tone; some agents can precipitate vasodilatation and reflex tachycardia while others can cause bradycardia, particularly if used in combination with other vagotonic drugs. Ketamine can increase heart rate and blood pressure by increasing central sympathetic outflow. Also, ketamine is a direct myocardial depressant.^{2,3,10}

Oxygen and Carbon Dioxide Monitoring

Continuous pulse-oximetry to monitor oxygen saturation is mandatory. Supplemental oxygen is generally administered to help prevent arterial desaturation and to increase the margin of safety during sedation. End-tidal CO₂ monitoring (capnography) is a noninvasive method for monitoring respiratory rate and pattern and can help detect airway obstruction and hypoventilation, and is recommended during cases involving moderate and deep sedation and general anesthesia. Monitoring oxygen saturation alone can be misleading, especially in patients receiving supplemental oxygen. The elevated baseline arterial oxygen concentration allows a longer period of apnea to ensue before arterial desaturation falls low enough to prompt airway intervention. Capnography, on the other hand, provides instantaneous information about ventilation, perfusion, and metabolism.²⁻⁴

Blood Pressure Monitoring

Accurate monitoring of blood pressure is vital. Noninvasive automated cuff blood pressure devices are usually adequate in most EP procedures performed under minimal or moderate sedation. Invasive arterial pressure monitoring should be considered for unstable patients, those with severely compromised cardiac function, when periods of deep sedation are expected or planned, and during procedures with higher risk of complications with serious hemodynamic consequences (e.g., procedures involving transseptal left atrium [LA] access, scar-related VT ablation).²

Defibrillator Pads

A functioning cardioverter-defibrillator should be available at the patient's side throughout the EP study. Using preapplied adhesive defibrillator pads is preferred to avoid disrupting the sterile field in the event that electrical defibrillation or cardioversion is needed during the procedure. Biphasic devices are more effective than devices with monophasic waveforms.

Urinary Problems

Urinary retention can occur during lengthy EP procedures, particularly in combination with sedation, fluid administration, and tachycardia-related diuresis. When such situations are anticipated, it is useful to insert a urinary drainage catheter before the procedure.

Antiarrhythmic Drugs

Antiarrhythmic drugs are usually, but not always, stopped for at least five half-lives prior to EP testing. In selected cases, antiarrhythmic drugs can be continued if an arrhythmic event occurred while the patient was taking a specific agent.

Anticoagulation

Therapeutic levels of oral anticoagulation for 4 weeks before the procedure or transesophageal echocardiography (TEE) (to exclude the presence of intracardiac thrombus) are required before studying patients who have persistent AF and atrial flutter (AFL) who may have sinus rhythm restored intentionally or inadvertently (i.e., cardioversion of VT).

Periprocedural anticoagulation for catheter ablation of persistent AFL or AF is necessary to minimize thromboembolic stroke risk; LA stunning and increased spontaneous echo contrast within the LA can occur following cardioversion or ablation of these arrhythmias. Similarly, patients with a mechanical valvular prosthesis require uninterrupted anticoagulation.

A perception of increased bleeding risks of invasive procedures in patients taking therapeutic doses of oral anticoagulants led many operators to adopt a "bridging" strategy of conversion to enoxaparin

to allow ablation and subsequent hemostasis to be performed during a pause in anticoagulation. An alternative strategy of uninterrupted oral anticoagulation during these procedures was found to be safe and feasible and more cost-effective for ablation of typical AFL or AF, without increasing hemorrhagic complications. This anticoagulation strategy can potentially be used routinely for EP studies and ablation of other arrhythmias when interruption of anticoagulation poses a significant risk.

Anticoagulation with heparin (or bivalirudin in patients allergic to heparin) is necessary for all left heart procedures, even in patients on uninterrupted oral anticoagulation. For right heart procedures, there is no evidence favoring routine use of anticoagulation, unless in individual patients at particularly high risk for thromboembolism.¹

CATHETERIZATION TECHNIQUES

Electrode Catheters

Electrode catheters are used during EP testing for recording and pacing. These catheters consist of insulated wires; at the distal tip of the catheter, each wire is attached to an electrode, which is exposed to the intracardiac surface. At the proximal end of the catheter, each wire is attached to a plug, which can be connected to an external recording device. Electrode catheters are generally made of woven Dacron or newer synthetic materials, such as polyurethane. The Dacron catheters have the advantage of stiffness, which helps maintain catheter shape with enough softness at body temperature to allow formation of loops. Catheters made of synthetic materials cannot be easily manipulated and change shape within the body, but they are less expensive and can be made smaller. Some manufacturers use braided metal strands to enhance torque control.

Electrode catheters come in different sizes (3 to 8 Fr). In adults, sizes 5, 6, and 7 Fr catheters are the most commonly used. Recordings derived from electrodes can be unipolar (one pole) or bipolar (two poles). The electrodes are typically 1 to 2 mm in length. The interelectrode distance can range from 1 to 10 mm or more; catheters with a 2- or 5-mm interelectrode distance are most commonly used.

Many multipolar electrode catheters have been developed to facilitate placement of the catheter in the desired place and to fulfill various recording requirements. Bipolar or quadripolar electrode catheters are used to record and pace from specific sites of interest within the atria or ventricles. These catheters come with a variety of preformed distal curve shapes and sizes (eFig. 4.1). Multipolar recording electrode catheters are placed within the coronary sinus (CS) or along the crista terminalis in the right atrium (RA). The Halo catheter is a multipolar catheter used to map atrial electrical activity around the tricuspid annulus during atrial tachycardias, as well as for locating right-sided bypass tracts (BTs) (Fig. 4.1). A multipolar catheter with a distal ring configuration is used to record electrical activity from the pulmonary veins (PVs) (Fig. 4.2). The star-shaped multielectrode PentaRay is a 7 Fr steerable catheter with 20 electrodes distributed over 5 soft, radiating spines, allowing for rapid and high-density mapping (see Fig. 4.2). Basket catheters capable of conforming to the chamber size and shape have also been used for mapping atrial and ventricular arrhythmias (Fig. 4.3). Special catheters are also used to record LA and left ventricular (LV) epicardial activity from the CS branches.

Catheters can have a fixed or deflectable tip. Steerable catheters allow deflection of the tip of the catheter in one or two directions in a single plane; some of these catheters have asymmetrical bidirectional deflectable curves (eFig. 4.2).

Ablation catheters have tip electrodes that are conventionally 4 mm long and are available in sizes up to 10 mm in length (eFig. 4.3). The larger tip electrodes on ablation catheters reduce the resolution of a map obtained using recordings from the distal pair of electrodes.

Catheter Positioning

The percutaneous technique is used almost exclusively. RA, His bundle (HB), and right ventricular (RV) electrograms are most commonly recorded using catheters inserted via a femoral vein. Some other areas (e.g., the CS) are more easily reached through the superior vena cava (SVC), although the femoral approach can be adequate in most cases. Insertion sites can also include the internal jugular and subclavian veins. Femoral arterial access can be required for mapping of the LV or mitral annulus or for invasive blood pressure monitoring. Occasionally, an epicardial approach is required to map and ablate certain VTs and BTs as well as the sinus node. For this purpose, the epicardial surface is accessed via the CS and its branches or percutaneously (subxiphoid puncture).

eFig. 4.3 Ablation Catheters With Different Tip Electrode Sizes and Shapes. *Left to right*, Peanut 8-, 4-, 8-, and 10-mm tip electrodes. (Courtesy Boston Scientific, Boston, MA, United States.)

Fluoroscopy is conventionally used to guide intracardiac positioning of the catheters. It is important to remember that catheters can be withdrawn without fluoroscopy (an exception being when permanent pacemaker or implantable cardioverter-defibrillator [ICD] leads are in place), but they should always be advanced under fluoroscopic guidance. More recently, newer navigation systems have been tested to guide catheter positioning in an effort to limit radiation exposure (see Chapter 6).

Transcaval Approach

The modified Seldinger technique is used to obtain multiple venous accesses. The femoral approach is most common, but the subclavian, internal jugular, or brachial approaches may be used, most often for the placement of a catheter in the CS.

Fig. 4.3 Basket Catheters. *Left*, Basket catheter (Constellation) with eight equidistant, flexible, self-expanding splines; each spline contains eight 1.5-mm electrodes. *Right*, Mini-basket catheter (Orion) with eight splines, each containing eight very small electrodes (surface area, 0.4 mm²). (Image provided courtesy of Boston Scientific. © 2018 Boston Scientific Corporation or its affiliates. All rights reserved.)

Ultrasound guidance is recommended for cannulation of the internal jugular veins. Recent studies have also shown potential benefit of ultrasound-guidance for femoral vein puncture in reducing vascular complications, particularly in the setting of anticoagulation. Ultrasound imaging allows direct visualization of peripheral arterial and venous anatomy and assessment of variations in the spatial relationship between the common femoral vein and the adjacent common femoral artery.^{13–15}

The femoral access should be avoided in patients with any of the following: known or suspected femoral vein or inferior vena cava (IVC) thrombosis, active lower extremity thrombophlebitis or postphlebotic syndrome, groin infection, bilateral leg amputation, extreme obesity, or severe peripheral vascular disease resulting in nonpalpable femoral arterial pulse. IVC umbrella filters are not necessarily a contraindication to the femoral approach.

Typically, the RA, HB, and RV catheters are introduced via the femoral veins. It is advisable to use the left femoral vein for diagnostic EP catheters and to save the right femoral vein for potential ablation or mapping catheter placement, which then would be easier to manipulate because it would be on the side closer to the operator. Multiple venous punctures and single vascular sheaths may be used for the different catheters. Alternatively, a single triport 12 Fr sheath can be used to introduce up to three EP catheters (usually the RA, HB, and RV catheters). The CS catheter is frequently introduced via the right internal jugular or subclavian vein, but also via the femoral approach.

Right Atrial Catheter

A fixed-tip, 5 or 6 Fr quadripolar electrode catheter is typically used. The RA may be entered from the IVC or SVC. The femoral veins are the usual entry sites. Most commonly, stimulation and recording from the RA is performed by placing the RA catheter tip at the high posterolateral wall at the SVC-RA junction in the region of the sinus node or in the RA appendage (Fig. 4.4).

Right Ventricular Catheter

A fixed-tip, 5 or 6 Fr quadripolar electrode catheter is typically used. All sites in the RV are accessible from any venous approach. The RV apex is most commonly chosen for stimulation and recording because of stability and reproducibility (see Fig. 4.4).

Fig. 4.4 Fluoroscopic Views of Catheters in Study for Supraventricular Tachycardia. Catheters are labeled high right atrium (RA), right ventricle (RV), and coronary sinus (CS); the CS catheter was inserted from a jugular venous approach. HB, His bundle; LAO, left anterior oblique; RAO, right anterior oblique.

His Bundle Catheter

A fixed- or deflectable-tip, 6 Fr quadripolar electrode catheter is typically used. The catheter is passed via the femoral vein into the RA and across the tricuspid annulus until it is clearly in the RV (under fluoroscopic monitoring, using the right anterior oblique [RAO] view) (see Fig. 4.4). It is then withdrawn across the tricuspid orifice while maintaining a slight clockwise torque for good contact with the septum until a His potential is recorded. Initially, a large ventricular electrogram can be observed; then, as the catheter is withdrawn, the right bundle (RB) potential can appear (manifesting as a narrow spike less than 30 milliseconds before the ventricular electrogram). When the catheter is further withdrawn, the atrial electrogram appears and grows larger. The His potential usually appears once the atrial and ventricular electrograms are approximately equal in size and is manifest as a biphasic or triphasic deflection interposed between the local atrial and ventricular electrograms. If the first pass was unsuccessful, the catheter should be passed again into the RV and withdrawn with a slightly different rotation. If, after several attempts, a His potential cannot be recorded using a fixed-tip catheter, the catheter should be withdrawn and reshaped, or it may be exchanged with a deflectable-tip catheter. Once the catheter is in place, a stable recording can usually be obtained. Occasionally, continued clockwise torque on the catheter shaft is required to obtain a stable HB recording, which can be accomplished by looping the catheter shaft remaining outside the body and fixing the loop by placing a couple of towels on it, or by twisting the connection cable in the opposite direction so that it maintains a gentle torque on the catheter.

When the access is from the SVC, it is more difficult to record the His potential because the catheter does not lie across the superior margin of the tricuspid annulus. In this case, a deflectable-tip catheter is typically used, advanced into the RV, positioned near the HB region by deflecting the tip superiorly to form a J shape, and then withdrawing the catheter so that it lies across the superior margin of the tricuspid annulus. Alternatively, the catheter can be looped in the RA (“figure-of-6” position); then the body of the loop is advanced into the RV so that the tip of the catheter is pointing toward the RA and lying on the septal aspect of the RA. Gently withdrawing the catheter can increase the size of the loop and allow the catheter tip to rest on the HB location.

Recording of the HB electrogram can also be obtained via the retrograde arterial approach. Using this approach, the catheter tip is positioned in the noncoronary sinus of Valsalva (just above the aortic valve) or in the left ventricular outflow tract (LVOT), along the interventricular septum (just below the aortic valve).

Coronary Sinus Catheter

A femoral, internal jugular, or subclavian vein can be used to access the CS. It is easier to cannulate the CS using the right internal jugular or left subclavian vein versus the femoral vein because the CS valve is oriented anterosuperiorly and, when prominent, can prevent easy access to the CS from the femoral venous approach. A fixed-tip, 6 Fr decapolar electrode catheter is typically used for access from the SVC, whereas a deflectable-tip catheter is preferred for CS access from the femoral veins.

The standardized RAO and left anterior oblique (LAO) fluoroscopic views are used to guide placement of catheters in the CS. Although the CS cannot be directly visualized with standard fluoroscopy, the epicardial fat found in the posteroseptal space just posterior to the CS ostium (os) can be visualized as a characteristic radiolucency on cine fluoroscopy in the RAO projection, where the cardiac and diaphragmatic silhouettes meet.

When cannulating the CS from the SVC approach, the LAO view is used, the catheter tip is directed to the left of the patient, and the catheter is advanced with some clockwise torque to engage the CS os; electrodes should resemble rectangles rather than ovals when the catheter tip is properly oriented to advance into the CS. Once the CS os is engaged, the catheter is further advanced gently into the CS, so that the most proximal electrodes lie at the CS os (see Fig. 4.4).

During cannulation of the CS from the IVC approach, the tip of the catheter is first placed into the RV, in the RAO fluoroscopy view, and flexed downward toward the RV inferior wall. Subsequently, the catheter is withdrawn until it lies at the inferoseptal aspect of the tricuspid annulus. In the LAO or RAO view, the catheter is then withdrawn gently with clockwise rotation until the tip of the catheter drops into the CS os. Afterward, the catheter is advanced into the CS concomitantly with gradual release of the catheter curve (Fig. 4.5). Alternatively, the tip of the catheter is directed toward the posterolateral RA wall and

Fig. 4.5 Fluoroscopic Views of Catheters in a Study of Typical Atrial Flutter. A 20-pole Halo catheter is positioned along the tricuspid annulus. The coronary sinus (CS) catheter was introduced from a femoral venous approach. The ablation catheter (Abl) is at the cavotricuspid isthmus. LAO, Left anterior oblique; RAO, right anterior oblique.

advanced with a tight curve to form a loop in the RA, in the LAO view, with the tip directed toward the inferomedial RA. The tip is then advanced with gentle up-down, right-left manipulation using the LAO and RAO views to cannulate the CS. In the RAO view, the atrioventricular (AV) fat pad (containing the CS) appears as more radiolucent than surrounding heart tissue.

When attempting CS cannulation, the catheter can enter the RV, and premature ventricular complexes (PVCs) or VT can be observed. Catheter position in the right ventricular outflow tract (RVOT) can be misleading and simulate a CS position. Confirming appropriate catheter positioning in the CS can be achieved by fluoroscopy and recorded electrograms. In the LAO view, further advancement in the CS directs the catheter toward the left heart border, where it curves toward the left shoulder. Conversely, advancement of a catheter lying in the RVOT leads to an upward direction of the catheter toward the pulmonary artery. In the RAO view, the CS catheter is directed posteriorly, posterior to the AV sulcus, whereas the RVOT position is directed anteriorly. Recording from the CS catheter shows simultaneous atrial and ventricular electrograms, with the atrial electrogram falling in the later part of the P wave, whereas a catheter lying in the RVOT records only a ventricular electrogram. The catheter can also pass into the LA via a patent foramen ovale, in which case it takes a straight course toward the left shoulder, and all recordings are atrial.

If used, the CS catheter should be placed first because its positioning can be impeded by the presence of other catheters. It is also recommended that the CS catheter sheath be sutured to the skin to prevent displacement of the catheter during the course of the EP study.

Transaortic Approach

This approach is generally used for mapping the LV and mitral annulus (for VT and left-sided BTs). The right femoral artery is most commonly used. The mapping-ablation catheter is passed to the descending aorta. If any resistance to catheter advancement occurs, it should not be forced; the tip can be withdrawn a few centimeters, deflected and torqued slightly, and another attempt made at advancing it. If several attempts do not allow access to the descending aorta, this approach should be abandoned, since even if one is able to manipulate the catheter through tortuous vessels, torque control of the tip within the LV is likely to be severely restricted. A solution is use of a long vascular sheath; the catheter is removed from the short sheath, and a long guidewire placed in it to ascertain if it passes smoothly into the distal aorta. If so, a long sheath can be advanced over the guidewire and the catheter can then be safely passed through the sheath into the aorta. If access to the aorta via the right femoral artery is impossible or unsafe, the left femoral artery can be used.

Once the catheter tip is in the central aorta, movement proximally toward the heart is usually relatively smooth (although side branches and atheromas can be encountered). In this position, a tight J curve is formed with the catheter tip before passage to the aortic root to minimize catheter manipulation in the arch. In a 30-degree RAO view, the curved catheter is advanced through the aortic valve with the J curve opening to the right, so the catheter passes into the LV oriented anterolaterally (eFig. 4.4). The straight catheter tip must never be used to cross the aortic valve because of the risk of leaflet damage or perforation and also because the catheter tip can slip into the left or right coronary artery or a coronary bypass graft, thus mimicking entry to the LV and causing damage to these structures.

In addition to facilitating catheter passage through a tortuous iliac artery, the use of a long sheath (e.g., SL0 or SL1; 81 cm; St. Jude Medical, St. Paul, MN, United States), with the tip of the sheath placed through the aortic valve into the LV, can provide added catheter stability and limit catheter dislodgement out of the LV.

Anticoagulation with IV heparin should be started once the LV is accessed or before, to maintain the activated clotting time (ACT) between 250 and 350 seconds.

Transseptal Approach

The atrial transseptal approach is utilized for mapping and ablation in the LA and has also been increasingly used for accessing the LV. A search for a patent foramen ovale, which is present in 15% to 20% of normal subjects, is initially performed by probing the septum from the inferior approach. If no opening is found, atrial septal puncture is performed. Several approaches have been described to achieve a safe and successful transseptal puncture. The challenge for a successful atrial septal puncture is positioning the Brockenbrough needle at the thinnest aspect of the atrial septum, the membranous fossa ovalis, guided by fluoroscopy or intracardiac echocardiography (ICE).

Anatomical Considerations

Knowledge of septal anatomy and its relationship with adjacent structures is essential to ensure safe and effective access to the LA. Many apparent atrial septal structures are not truly septal. The true interatrial septum is limited to the floor of the fossa ovalis (primary septum), the flap valve, and the anteroinferior rim of the fossa. Therefore the floor of the fossa (with an average diameter of 18.5 ± 6.9 mm [vertically] and 10.0 ± 2.4 mm [horizontally] and 1 to 3 mm in thickness) is the target for atrial septal crossing (Fig. 4.6). The area between the superior border of the fossa and the mouth of the SVC is an infolding of the atrial musculature filled with adipose tissue (corresponding to the pericardial transverse sinus and the anterosuperior interatrial groove). Although this area is often described incorrectly as the “septum

Fig. 4.6 Anatomy of the Atrial Septum. En face view of the atrial septum, observed from a 35 right anterior oblique view. Ao, Ascending aorta; CS, coronary sinus; ER, eustachian ridge; ICV, inferior caval vein; MS, membranous septum; N, noncoronary aortic sinus; OF, oval fossa; R, right coronary aortic sinus; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein; RV, right ventricle; SCV, superior caval vein; TVA, tricuspid valve attachment. eFig. 4.4 Fluoroscopic Views of a Mapping-Ablation Catheter Introduced Into the Left Ventricle (LV) via the Retrograde Transaortic Approach. In a 30-degree right anterior oblique view, the curved catheter (A) is prolapsed across the aortic valve into the LV (B).

secundum,” it is not really a true septum, and puncture in this region would lead to exiting the heart. The infolded groove ends at the superior margin (superior rim) of the fossa ovalis. The anteroinferior muscular buttress anchors the primary septum to the muscular ventricular septum and attaches to the central fibrous body (which is composed of the right fibrous trigone and the AV portion of the membranous septum) just beneath the noncoronary aortic sinus. Anterior and superior to the fossa ovalis, the RA wall overlies the aortic root. Advancing the transseptal needle in this area can puncture the aorta.¹⁶

Understanding the attitudinal anatomical relationships of the atrial septum and adjacent structures as well as the fluoroscopic anatomy based on conventional landmarks is critical for a safe and successful transseptal puncture procedure. When the heart is viewed in an attitudinally correct orientation (as it lies within the chest), the RA lies rightward and anterior, while the LA lies posterior, leftward, and slightly superior in relation to the RA. The aortic root runs along the anterior aspect of the interatrial septum (Fig. 4.7). The fossa ovalis is located inferior and posterior relative to the noncoronary aortic sinus, and posterior to the triangle of Koch. The plane of the interatrial septum is slanted from left anterior to right posterior, with a mean orientation of 37 degrees, but can vary from 19 to 53 degrees. The orientation of the atrial septum orientation was found to strongly correlate with the direction of the CS, despite a wide range of variability in our patient population. Hence, typically the interatrial septum is almost perpendicular to the plane of the screen in the LAO 50- to 60-degree projection angle, and horizontal in the RAO 30- to 40-degree projection angle. However, adjustment of the RAO and LAO projection angles can be required to account for

rotation of the interatrial septum observed in some patients. This can be facilitated by aligning the RAO projection to an angle where the proximal part of CS catheter lies perpendicular to the screen or a His recording catheter is pointing directly toward the screen.¹⁷

Anticoagulation

Anticoagulation is essential for prevention of thromboembolism during any left-sided heart catheterization. Current recommendations advocate that IV heparin bolus be administered immediately after or, preferably, just before puncturing the atrial septum, followed by intermittent boluses or continuous heparin infusion to maintain an elevated ACT (300 to 400 seconds), even in patients on uninterrupted therapeutic doses of oral anticoagulation. However, recent evidence found that unfractionated heparin displays unexpected slow anticoagulation kinetics in a significant proportion of patients for up to 20 minutes after infusion (reflected in ACTs less than 300 seconds). Hence, some investigators have suggested administering IV heparin at least 10 minutes *before* transseptal puncture and assessing ACT at 10 minutes with an additional unfractionated heparin infusion in patients with subtherapeutic ACT.^{18,19}

Fluoroscopy-Guided Transseptal Catheterization

Equipment required for atrial septal puncture includes the following: an 8 Fr transseptal sheath for LA cannulation (e.g., SR0, SL series, Mullins, or Agilis NxT Steerable sheath, St. Jude Medical, Minnetonka, MN, United States), a 0.032-inch J guidewire, a Brockenbrough needle (e.g., BRK, St. Jude Medical), and a 190-cm, 0.014-inch guidewire. The transseptal sheaths and Brockenbrough needles are available in two

Fig. 4.7 Volume-Rendered Images of the Atrial Septum. (A) The “atrial septum” (AS) is merged with the fluoroscopy-like image. White arrows show the radiolucent band. Note that the oval fossa (OF), interatrial fold, and anteroinferior muscular buttress were reconstructed as one piece (red). Only the OF and muscular buttress are the true AS. (B) The ascending aorta (Ao), coronary sinus (CS), and middle coronary vein (MCV) are added. The yellow arrow indicates where the inferior free wall of the right atrium directly faces the inferior pyramidal space. AIV, Anterior interventricular vein; GCV, great cardiac vein; L, left coronary aortic sinus; LAO, left anterior oblique; N, noncoronary aortic sinus; R, right coronary aortic sinus; RAO, right anterior oblique. Clinical cardiac structural anatomy reconstructed within the cardiac contour using multidetector-row computed tomography: atrial septum and ventricular septum. *Clin Anat*. 2016;29:342–352.)

different lengths; it is important to ensure that the length of needle matches that of the sheath.

Venous access is obtained via the femoral vein, preferably the right femoral vein because it is closer to the operator. The sheath, dilator, and guidewires are flushed with heparinized saline. The transseptal sheath-dilator assembly is advanced over a 0.032-inch J guidewire under fluoroscopy guidance into the SVC (to the level of the tracheal carina). The guidewire is then withdrawn, thus leaving the sheath and its dilator locked in place. The dilator within the sheath is flushed and attached to a syringe to avoid introduction of air into the RA.

Attention is then directed to preparing the transseptal needle. The Brockenbrough needle comes prepackaged with an inner stylet, which may be left in place to protect it as it is advanced within the sheath. Alternatively, the inner stylet may be removed and the needle connected to a pressure transducer line (pressure monitoring through the Brockenbrough needle will be required during the transseptal puncture); continuous flushing through the Brockenbrough needle is used while advancing the needle into the dilator. A third approach, when the use of contrast injection is planned, is to attach the Brockenbrough needle to a standard three-way stopcock via a freely rotating adapter. A 10-mL syringe filled with radiopaque contrast is attached to the other end of the stopcock while a pressure transducer line is attached to the third stopcock valve for continuous pressure monitoring. The entire apparatus should be vigorously flushed to ensure that no air bubbles are present within the circuit.

Before making an attempt at puncturing the atrial septum, it is important to ensure that all equipment is working properly, especially the pressure transducer attached to the needle. If this detail is not attended to prior to the septal puncture attempt, it becomes difficult to interpret a flat pressure tracing when the needle tip is supposedly in the LA cavity. This may mean the needle is in fact in the LA but the stopcock on the pressure tubing is turned incorrectly, or that the wrong tubing was connected to the needle hub, or that the needle tip is not in the LA. Assuring that the pressure system is working properly by “flicking” the needle shaft and seeing its corresponding pressure reverberation waveform obviates uncertainty as to whether the connections are correct. In addition, taking note of baseline blood pressure and appearance of the left heart border on fluoroscopy are important for reference; unanticipated decreases in blood pressure or decreased motion of the left heart border, compared to baseline, may be early clues to a developing pericardial effusion.

Engaging the fossa ovalis. The Brockenbrough needle is advanced into the dilator until the needle tip is within 1 to 2 cm of the dilator tip. The needle tip must be kept within the dilator at all times, except during actual septal puncture. This can be ensured by holding the sheath-dilator assembly by the left hand, and holding the needle by the right hand, while minding a safe distance of the proximal needle hub from the dilator. The curves of the dilator, sheath, and needle (as indicated by the side port of the sheath and the pointer on the proximal hub of the needle) should be aligned so that they are all in agreement and not contradicting each other. The sheath, dilator, and needle assembly is then rotated leftward and posteriorly (usually with the Brockenbrough needle arrow pointing at the 3 to 6 o'clock position relative to its shaft) and retracted caudally as a single unit (while maintaining the relative positions of its components) to engage the tip of the dilator into the fossa ovalis. Under fluoroscopy monitoring (30-degree LAO view), the dilator tip moves slightly leftward on entering the RA and then leftward again while descending below the aortic root. A third abrupt leftward movement (“jump”) below the aortic root indicates passage over the limbus into the fossa ovalis (Fig. 4.8). This jump generally occurs at the level of the HB region (marked by an EP catheter recording the HB potential). If the sheath and dilator assembly is pulled back farther than

Fig. 4.8 Fluoroscopic Views During Transseptal Catheterization. Right anterior oblique (RAO, left panels) and left anterior oblique (LAO, right panels) are shown. (A) Initially, the transseptal sheath-dilator assembly is advanced into the superior vena cava. (B) The transseptal assembly is withdrawn into the high right atrium. (C) With further withdrawal, the dilator tip abruptly moves leftward, indicating passage over the limbus into the fossa ovalis at the level of the His bundle catheter. At the fossa ovalis, the dilator tip has an anteroposterior orientation in the RAO view and a leftward orientation in the LAO view. (D) The transseptal assembly is advanced across the atrial septum. CS, Coronary sinus.

intended (i.e., below the level of the fossa and HB region), the needle should be withdrawn and the guidewire placed through the dilator into the SVC. The sheath and dilator assembly is then advanced over the guidewire into the SVC and repositioning attempted, as described earlier. The sheath and dilator assembly should never be advanced without the guidewire at any point during the procedure.

Confirming position at the fossa ovalis. Several fluoroscopic markers are used to confirm the position of the dilator tip at the fossa ovalis. As noted, an abrupt leftward movement (jump) of the dilator tip below the aortic knob is observed (in the LAO view) as the tip passes under the muscular atrial septum onto the fossa ovalis. In addition, the posterior extent of the aortic root can be marked by a pigtail catheter positioned through the femoral artery in the noncoronary cusp or by the HB catheter (recording a stable proximal HB potential), which lies at the level of the fibrous trigone opposite and caudal to the noncoronary aortic cusp. When the dilator tip lies against the fossa ovalis, it is directed posteroinferiorly to the proximal HB electrode (or pigtail catheter) in the RAO view and to the left of the proximal HB electrode (or pigtail catheter) in the LAO view (see Fig. 4.8). Another method that can be used to ensure that the tip is against the fossa ovalis is injection of 3 to 5 mL of radiopaque contrast through the Brockenbrough needle to visualize the interatrial septum. The contrast stains the fossa and the needle tip then can be seen tenting the fossa ovalis

membrane with small movements of the entire transseptal apparatus. Typically, septal staining remains visible after contrast injection, which allows for real-time septal visualization while monitoring the pressure during transseptal puncture.

Puncturing the septum. Once the position of the dilator tip is confirmed at the fossa ovalis, the sheath-dilator-needle assembly is pushed slightly against the interatrial septum, and the needle is then briskly advanced to protrude outside the dilator in the LAO view during continuous pressure monitoring. If excessive force is applied without a palpable “pop” to the fossa, then the Brockenbrough needle likely is not in proper position. Occasionally, pushing the sheath-dilator-needle assembly against the fossa ovalis results in sliding of the whole assembly up the interatrial septum rather than tenting of the fossa ovalis. Increasing the “reach” of the transseptal needle tip by curving the shaft 15 to 20 back from the tip (achieved by manual adjustment) or of the sheath (when a deflectable transseptal sheath is utilized) can help mitigate this problem.

Confirming position in the LA. After passage through the fossa ovalis and before advancing the dilator and sheath, an intraatrial position of the needle tip within the LA, rather than the ascending aorta or posteriorly into the pericardial space, needs to be confirmed. Recording an LA pressure waveform from the needle tip confirms an intraatrial location (Fig. 4.9). An arterial pressure waveform indicates intraaortic

Fig. 4.9 Fluoroscopic Views and Simultaneous Electrical and Pressure Recordings During Transseptal Catheterization. *Left*, The transseptal assembly is in the right atrium (RA), indicated by typical A and V waves of right-heart pressure tracing. *Middle*, The pressure waveform is dampened somewhat as the catheter tip abuts the septum. *Right*, The needle is across the atrial septum, and characteristic waves (V larger than A) are seen. CS, Coronary sinus; CS_{dist}, distal coronary sinus; CS_{prox}, proximal coronary sinus; LA, left atrium; LAO, left anterior oblique; P, pressure.

position of the needle. Absence of a pressure wave recording can indicate needle passage into the pericardial space or sliding up and not puncturing through the atrial septum. A second method is injection of contrast through the needle to assess the position of the needle tip. Opacification of the LA (rather than the pericardium or the aorta) verifies the successful transseptal access. Alternatively, passing a 0.014-inch floppy guidewire through the Brockenbrough needle into a left-sided PV (beyond the cardiac silhouette in the LAO fluoroscopy view) helps verify that needle tip position is within the LA. If the guidewire cannot be advanced beyond the fluoroscopic border of the heart, atrial free-wall puncture with pericardial needle location should be suspected. In addition, aortic puncture should be suspected if the guidewire seems to follow the course of the aorta. In these situations, contrast should be injected to assess the position of the Brockenbrough needle before advancing the transseptal dilator. Sometimes, the guidewire enters the LA appendage rather than a PV; in this setting, a clockwise torque of the sheath and dilator assembly can help direct the guidewire posteriorly toward the ostium of the left superior or left inferior PV.

Once the position of the needle tip is confirmed to be in the LA, both the sheath and dilator are advanced as a single unit over the needle by using one hand while fixing the Brockenbrough needle in position with the other hand (to prevent any further advancement of the needle). Preferably, the sheath-dilator assembly is advanced into the LA over a guidewire placed distally into a left-sided PV, which helps direct the path of the assembly as it enters the LA and minimize the risk of inadvertent puncture of the LA free wall, especially in the presence of an elastic or redundant septum that can suddenly release, resulting in a significant forward lurch of the dilator and sheath. Once the dilator tip is advanced into the LA over the needle tip, the needle and dilator are firmly stabilized as a unit—to prevent any further advancement or withdrawal of the needle and dilator—and the sheath is advanced over the dilator into the LA. It is important to keep the needle across the septum at this time to facilitate advancement of the sheath through the puncture site. In some cases, the septum is very stiff (after prior transseptal procedures, especially) and attempts to advance the sheath into the LA result in bowing of the assembly in the RA, risking “backing out” of the dilator from the LA. In such cases, rotating the entire apparatus such that the dilator points toward the head or right superior PV can facilitate passage of the sheath through the septum, since the pushing force administered along the long axis of the assembly is now transmitted in line with the intended direction of the sheath tip (as opposed to pushing from the groin and hoping the sheath advances more sideways, toward the left shoulder). Once the transseptal sheath tip is within the LA, the dilator and needle are withdrawn slowly during continuous flushing through the needle or while suction is maintained through a syringe placed on the sheath side port to minimize the risk of air embolism and while fixing the sheath with the other hand to prevent dislodgment outside the LA. The sheath should be aspirated until blood appears without further bubbles; this usually requires aspiration of approximately 5 mL and sometimes “flicking” the sheath hub with a finger is needed to dislodge trapped air. The sheath is then flushed with heparinized saline at a flow rate of 3 mL/min during the entire procedure.

The mapping-ablation catheter is advanced through the sheath into the LA. This is safely done by advancing the catheter tip to the tip of the sheath, and while holding the catheter steady, withdrawing the sheath slightly over the catheter, exposing about 2 cm of the catheter tip. In so doing, one ensures that the catheter (stiffened by being inside the sheath) does not perforate the atrial wall. Flexing the catheter tip and applying clockwise and counterclockwise torque to the sheath help confirm free movement of the catheter tip within the LA, rather than possibly in the pericardium. It is important to recognize that merely recording atrial electrograms does not confirm an LA catheter location

because an LA recording can be obtained from the epicardial surface of the LA, from the RA, or even the aortic root.

Second transseptal puncture. When two transseptal accesses are required, the second access can be obtained through a separate transseptal puncture performed in a fashion similar to that described for the first puncture. Alternatively, the first transseptal puncture can be used for the second sheath. This technique entails passing a guidewire or thin catheter through the first transseptal sheath into the LA, preferably into the left inferior or superior PV, and then the sheath is pulled back into the RA. Subsequently, a deflectable tip catheter is used through the second transseptal sheath to interrogate the fossa ovalis and to try to access the LA through the initial puncture site. Once this is accomplished, the first sheath is advanced back into the LA, and the guidewire is replaced with the mapping catheter. It is also possible to advance two guidewires through the first transseptal sheath into the LA (preferably into the left inferior or superior PV). The sheath is then pulled out, and a separate transseptal sheath is advanced over each of the two guidewires. This requires both sheaths to go through the same femoral puncture site, which can increase bleeding in the presence of significant anticoagulation.

Intracardiac Echocardiography–Guided Transseptal Catheterization

Although fluoroscopy provides sufficient information to allow safe transseptal puncture in most cases, variations in septal anatomy, atrial or aortic root dilation, the need for multiple punctures, and the desired ability to direct the catheter to specific locations within the LA can make fluoroscopy inadequate for complex LA ablation procedures. Intraoperative TEE allows identification of the fossa ovalis and its relation to surrounding structures and provides real-time evaluation of the atrial septal puncture procedure, with demonstration of tenting of the fossa prior to entry into the LA and visualization of the sheath advancing across the septum. However, the usefulness of TEE is limited by the fact that the probe obstructs the fluoroscopic field, and it is impractical in the unanesthetized patient. ICE, which provides similar information on septal anatomy, can be used for the conscious patient and does not impede fluoroscopy.

The intent of ICE-guided transseptal catheterization is to image intracardiac anatomy and identify the exact position of the distal aspect of the transseptal dilator along the atrial septum—in particular, to assess for tenting of the fossa ovalis with the dilator tip.

Two types of ICE imaging systems are currently available: the electronic phased-array ultrasound catheter and the mechanical ultrasound catheter. The phased-array ultrasound catheter sector imaging system (AcuNav, Siemens Medical Solutions, Malvern, PA, United States) uses an 8 or 10 Fr catheter that has a forward-facing 64-element vector phased-array transducer scanning in the longitudinal plane. The catheter has a four-way steerable tip (160 degree anteroposterior or left-right deflections). The catheter images a sector field oriented in the plane of the catheter. The mechanical ultrasound catheter radial imaging system (Ultra ICE, EP Technologies, Boston Scientific, San Jose, CA, United States) uses a 9-MHz catheter-based ultrasound transducer contained within a 9 Fr (110-cm length) catheter shaft. It has a single rotating crystal ultrasound transducer that images circumferentially for 360 degrees in the horizontal plane. The catheter is not freely deflectable.

When using the mechanical radial ICE imaging system, a 9 Fr sheath (preferably a long, preshaped sheath) for the ICE catheter is advanced via a femoral venous access. To enhance image quality, all air must be eliminated from the distal tip of the ICE catheter by flushing vigorously with 5 to 10 mL of sterile water. The catheter then is connected to the ultrasound console and advanced until the tip of the rotary ICE catheter images the fossa ovalis. Satisfactory imaging of the fossa

ovalis for guiding transseptal puncture is viewed from the mid-RA (Fig. 4.10).

The AcuNav ICE catheter is introduced under fluoroscopy guidance through a 23-cm femoral venous sheath. Once the catheter is advanced into the mid-RA with the catheter tension controls in neutral position (the ultrasound transducer oriented anteriorly and to the left), the RA, tricuspid valve, and RV are viewed. This is called the home view (Fig. 4.11A). Gradual clockwise rotation of a straight catheter from the home view allows sequential visualization of the aortic root and the pulmonary

Fig. 4.10 Intracardiac Echocardiography (ICE)-Guided Transseptal Puncture Using the Ultra-ICE Catheter. These ICE images are obtained with the transducer placed in the right atrium (RA). (A) The RA, fossa ovalis (arrowheads), left atrium (LA), and aorta (AO) are visualized. (B) The transseptal needle is properly positioned, with tenting (yellow arrow) against the mid-interatrial septum at the fossa ovalis. RV, Right ventricle.

artery (see Fig. 4.11B), followed by the CS, the mitral valve, the LA appendage orifice, and a cross-sectional view of the fossa ovalis (see Fig. 4.11C and D). The mitral valve and interatrial septum are usually seen in the same plane as the LA appendage. Posterior deflection or right-left steering of the imaging tip in the RA, or both, is occasionally required to optimize visualization of the fossa ovalis; the tension knob (lock function) can then be used to hold the catheter tip in position. Further clockwise rotation beyond this location demonstrates images of the left PV ostia (see Fig. 4.11E). The optimal ICE image to guide transseptal puncture demonstrates adequate space beyond the interatrial septum on the LA side and clearly identifies adjacent structures, but it does not include the aortic root because it would be too anterior for the interatrial septum to be punctured safely. In patients with an enlarged LA, a cross-sectional view that includes the LA appendage is also optimal if adequate space exists beyond the atrial septum on the LA side.

The sheath-dilator-needle assembly is introduced into the RA, and the dilator tip is positioned against the fossa ovalis, as described earlier. Before advancing the Brockenbrough needle, continuous ICE imaging should direct further adjustments in the dilator tip position until ICE confirms that the tip is in intimate contact with the middle of the fossa, confirms proper lateral movement of the dilator toward the fossa, and excludes inadvertent superior displacement toward the muscular septum and aortic valve. With further advancement of the dilator, ICE demonstrates tenting of the fossa (Figs. 4.10 and 4.12). If the distance from the tented fossa to the LA free wall is small, minor adjustments in the dilator tip position can be made to maximize the space. The Brockenbrough needle is then advanced. With successful transseptal puncture, a palpable pop is felt, and sudden collapse of the tented fossa is observed (see Fig. 4.12). Advancement of the needle is then

Fig. 4.11 Phased-Array Intracardiac Echocardiography (ICE). Phased-array ICE (AcuNav) serial images with the transducer placed in the middle right atrium (RA) demonstrate serial changes in tomographic imaging views following clockwise rotation of the transducer. Each view displays a left-right orientation marker to the operator's left side (i.e., craniocaudal axis projects from image right to left). (A) Starting from the home view, the RA, tricuspid valve (yellow arrowheads), and right ventricle (RV) are visualized. (B) Clockwise rotation brings the aorta (AO) into view. (C) Further rotation allows visualization of the interatrial septum (green arrows), left atrium (LA), coronary sinus (CS), left ventricle (LV), and mitral valve (red arrowheads). (D) Subsequently, the left atrium appendage (LAA) becomes visible. (E) The ostia of the left superior pulmonary vein (LSPV) and left inferior PV (LIPV) can be visualized with further clockwise rotation. PA, Pulmonary artery. (Courtesy AcuNav, Siemens Medical Solutions, Malvern, PA, United States.)

Fig. 4.12 Phased-Array Intracardiac Echocardiography (ICE)-Guided Transseptal Puncture. (A) These ICE images, with the transducer placed in the right atrium (RA), show a transseptal dilator tip (yellow arrow-head) lying against the interatrial septum (green arrows). (B) With further advancement of the dilator, ICE demonstrates tenting of the interatrial septum at the fossa ovalis. (C) Advancement of the transseptal needle is then performed, with the needle tip visualized in the left atrium (LA), and tenting of the interatrial septum is lost.

immediately stopped. Saline infusion through the needle is visualized on ICE as microbubbles in the LA, thus confirming successful septal puncture. With no change in position of the Brockenbrough needle, the transseptal dilator and sheath are advanced over the guidewire into the LA, as described earlier.

Alternative Methods for Difficult Transseptal Catheterization

In some cases, the conventional approach using a Brockenbrough needle sheath fails to pierce the septum because of the presence of a small fossa area, a thick interatrial septum, fibrosis and scarring of the septum from previous interventions, or an aneurysmal septum with excessive laxity. Applying excessive force to the needle-dilator-sheath assembly against a resistant septum (which can be seen as bending and buckling of the assembly in the RA) can lead to building pressure of the needle tip on the septum, which can potentially lead to an uncontrolled sudden jump of the assembly once across the fossa ovalis, thus perforating the opposing lateral LA wall. Similarly, excessive tenting of the interatrial septum (beyond halfway into the LA) can bring it in close proximity to the lateral LA wall, so that the needle can potentially puncture the lateral LA wall once across the septum. Some of these difficulties can be overcome by manual reshaping of the curvature of the Brockenbrough needle tip, applying slight rotation on the needle and sheath assembly to puncture a different point on the fossa ovalis, or using a sharper transseptal needle type (BRK-1 extra sharp).²⁰

Other tools designed specifically for transseptal puncture, including the SafeSept Transseptal Guidewire and the radiofrequency (RF)-powered needle, can help minimize pressure application to the needle as it crosses the septum and tenting of the septum, which can potentially reduce the chances of sudden advancement through the lateral LA as the needle crosses the septum.

SafeSept Transseptal Guidewire. The SafeSept Transseptal Guidewire (Pressure Products, San Pedro, CA, United States) is a 135-cm long, 0.014-inch diameter nitinol guidewire, tipped with a flexible J-curve needle specifically designed for transseptal puncture. Once the sheath-dilator-needle assembly is appropriately positioned at the fossa, and tenting of the fossa is seen on ICE, the SafeSept guidewire is advanced through the Brockenbrough needle to puncture the floor of the fossa with minimal force. The flexible J-curve needle then forms a loop (J curve) in the LA once it crosses the septum and is exposed out of the dilator, rendering it incapable of further tissue penetration. The transseptal needle, dilator and sheath are then sequentially advanced over the SafeSept wire into the LA.

A second iteration of this technique uses a 150-cm long, 0.032-inch diameter nitinol guidewire (SafeSept Needle Free Transseptal Guidewire) with a very sharp tip specifically designed to easily perforate and cross the fossa ovalis in conjunction with a transseptal sheath and dilator, but without the need for a transseptal needle. When the tip of the introducer has reached the fossa ovalis and tenting is seen on ICE, the guidewire is advanced, tapping on the interatrial septum until it pushes through the septum into the LA. Once across the septum, unsupported by the dilator and sheath, the tip of the guidewire assumes a J shape, rendering it incapable of further tissue penetration. The wire is then advanced into the left superior PV under fluoroscopic guidance, and the transseptal sheath-dilator assembly is advanced over the guidewire into the LA. A limitation of this technique, when compared to the Brockenbrough needle, is the lack of an open lumen to easily inject contrast or measure pressure.²¹

RF-powered needle. A specialized, electrically insulated RF-powered needle (Baylis Medical Company, Montreal, Canada) has been developed to facilitate transseptal puncture. The needle is connected to a proprietary RF generator (RFP-100 RF Puncture Generator, Baylis Medical), which delivers RF energy to the blunt, closed tip of the needle positioned at the atrial septum. Once septal tenting is visualized on ICE, RF energy is applied at 10 W for 2 seconds (unipolar mode). The RF perforation generators apply a high-voltage/low-power RF current from a small surface area of the embedded needle tip for short bursts, resulting in a high-energy electric field and an almost instantaneous temperature rise to 100°C, leading to steam popping and septal perforation with minimal collateral tissue damage (similar to the cut-mode of a surgical electrocautery unit). This can facilitate needle passage through atrial muscle with minimal—or at least reduced—mechanical pressure. This in contrast to conventional RF generators, which deliver a higher power with a lower voltage and impedance range for longer periods of time, with resulting thermal destruction of the local tissue around the needle tip, rather than perforation. The needle is also equipped with two distal side ports for measuring pressure and injecting contrast and fluids. The blunt tip of the RF needle offers an additional benefit. In contrast to the standard transseptal needle, advancing the blunt-tipped RF needle through the dilator is not associated with shaving off pieces of plastic from the inside of the dilator, which can potentially enter the patient's vascular system.^{22,23}

Other techniques to facilitate transseptal puncture include the application of pulses of electrosurgical cautery or RF energy to the proximal end of the Brockenbrough needle. Once the position of the dilator tip

is confirmed at the fossa ovalis (under ICE guidance), the needle is advanced beyond the tip of the dilator in contact with the septum until resistance is met. RF energy (5 to 30 W for 1 to 11 seconds) can be applied through a conventional ablation catheter electrode brought manually in contact with the proximal hub of the transseptal needle. Typically, the fossa is punctured almost instantaneously (within 1 to 2 seconds) following RF application. Alternatively, electrosurgical cautery (set to 15 to 20 W for a 1- to 2-second pulse of cut-mode cautery) is applied to the proximal hub of the needle as its tip is advanced out of the dilator. Importantly, the cautery should be initiated on the needle handle prior to pushing the needle tip beyond the dilator tip to help minimize the power needed to puncture the septum, and it should be stopped as soon as the needle is pushed out fully.²⁴

A potential disadvantage of using RF-assisted transseptal puncture is that it is more traumatic at the puncture site than a standard needle, and it is possible that the transseptal puncture site is less likely to close spontaneously after the procedure. Similarly, inadvertent cardiac perforation occurring in the setting of powered needles can potentially be associated with serious consequences. This is of a lesser concern when using the RF-powered Baylis needle, since it results in less tissue damage than that when applying electrosurgical cautery or standard RF energy to the Brockenbrough needle. Whether RF is more likely to cause a thrombus at the puncture site compared with a standard needle is unknown.

Another potential complication of applying electrocautery or RF energy to a standard open-ended Brockenbrough needle is coring (entrapment of a small plug) of septal atrial tissue into the tip of the open-ended Brockenbrough needle, which can lead to systemic embolization. In contrast, the Baylis needle is specifically designed with side holes, rather than an end-hole, to prevent coring.²⁵

Transseptal Puncture in the Presence of Atrial Septal Defect Repair

Transseptal catheterization is feasible and safe in most patients with prior surgical repair of an atrial septal defect or a patent foramen ovale. Nonetheless, because of the altered anatomical landmarks after repair, fluoroscopic guidance for transseptal puncture is not as reliable, and the procedure can be challenging. In these patients, an understanding of the method of repair and utilization of ICE guidance are essential.²⁰

In patients with a septal stitch or pericardial or Dacron patch, puncture can be achieved through the thickened septum or the patch. However, transseptal access is typically not achievable through a Gore-Tex patch (W.L. Gore & Associates, Flagstaff, AZ, United States) because of its resistant texture; instead, puncture can be performed directly through neighboring native interatrial tissue. However, when the patch is wide, sufficient free septal tissue for transseptal puncture may not be available, in which setting transseptal access to the LA may not be feasible.

In patients with atrial septal defect closure devices, puncture is preferably performed at the portion of the septum located inferior and posterior to the closure device and not through the device itself (eFig. 4.5). When areas of native septum are not available for transseptal access, recent reports described successful LA access through a direct puncture of the closure device.^{26,27}

Complications of Atrial Transseptal Puncture

Injury to cardiac and extracardiac structures is the most feared complication. Because of its stiffness and large caliber, the transseptal dilator should never be advanced until the position of the Brockenbrough needle is confirmed with confidence. Advancing the dilator into an improper location, such as the aortic root, can be fatal. Therefore many operators recommend the use of ICE-guided transseptal puncture, especially for patients with normal LA chamber size.²⁰

Cardiac perforation. Cardiac perforation, hemopericardium, and cardiac tamponade can result from puncturing the atrial wall outside the region of the fossa ovalis. In addition, perforation of the opposing posterior or lateral LA wall can occur once the transseptal assembly crosses the atrial septum, especially in the setting of excessive stiffness of the septum. Similarly, excessive tenting of the interatrial septum (beyond halfway into the LA) can bring it in close proximity to the lateral LA wall, so that the needle can potentially puncture the lateral LA wall once across the septum.²⁸ It is possible to puncture the RA free wall above the fossa and continue forward with the apparatus, puncturing back into the LA. In such a situation, sheath and catheter will be in the LA, but having achieved that position by exiting the heart and reentering it. This may not be noticed immediately, as the sheath may effectively occlude the holes it has traversed in the atrial walls, but will become evident when sheaths are withdrawn at the end of the procedure, leaving a hole in each atrium.

It is important to recognize that successful atrial septal puncture is a painless procedure for the patient. If the patient experiences significant discomfort, careful assessment should be made of the catheter and sheath locations (pericardial space, aorta).

Prompt recognition and management of cardiac perforation are critical to prevent the development of cardiac tamponade. Assessment of the cardiac silhouette fluoroscopically can provide the first clue, especially if a careful assessment was made at baseline. Decreased excursion of the lateral heart border on fluoroscopy in the LAO projection, indicating accumulating pericardial effusion, usually can be seen well before a decrease in blood pressure and prior to progression to cardiac tamponade. It is reasonable to obtain a baseline LAO cine image at the outset of a procedure to serve as a reference for comparison during the procedure, followed by intermittent evaluation of the same fluoroscopic projection during the procedure. Similarly, when ICE is utilized to guide transseptal puncture, it can be used to obtain baseline images of the LV and pericardial space before transseptal puncture and then monitor for the development of pericardial effusion afterwards. Importantly, bleeding into the pericardial space may develop only after the transseptal sheath has been removed. This may occur especially when the transseptal puncture is performed too superiorly or posteriorly, crossing the pericardial space (the anterosuperior interatrial groove) before entering the LA, as noted above.

The management of pericardial effusion is largely determined by its relative size and hemodynamic effect. Trivial pericardial effusions, if recognized early during the procedure, should be monitored continuously but do not warrant termination of the procedure. For larger effusions, the procedure should be terminated and anticoagulation, if administered, should be reversed. Protamine is used to reverse the effects of heparin, and activated factor VII, fresh frozen plasma, and vitamin K can be used in patients with therapeutic anticoagulation with warfarin. Immediate pericardiocentesis is required for large, rapidly expanding, or hemodynamically significant effusions.

Aortic puncture. When the aorta is adventerly punctured by the Brockenbrough needle—an arterial waveform is recorded from the needle tip and dye injected through the needle is carried away from the heart—the needle should be withdrawn back into the dilator. If only the needle enters the aorta and this is recognized before advancing the dilator and sheath, the needle can be withdrawn and the patient monitored for stability of vital signs and with echocardiography. The procedure can usually be continued if there is no accumulation of pericardial fluid after 15 to 30 minutes of monitoring. Advancing the dilator and sheath assembly into the aorta can lead to catastrophic consequences. If the dilator and sheath have been advanced into the aortic root before the error is recognized, it is imperative that the sheath not be removed immediately, as this can result in immediate and perhaps

eFig. 4.5 Transseptal Puncture in a Patient With Atrial Septal Defect Closure Device. A left anterior oblique fluoroscopic view shows the transseptal needle crossing the atrial septum at a site inferior to an Amplatzer occluder device, in a portion of the native interatrial septum not covered by the closure device. CS, Coronary sinus catheter; HB, His bundle catheter; RA, right atrial catheter.

irretrievable hemodynamic collapse due to intractable bleeding into the pericardial space. Once surgical intervention is readily available, and after reversal of anticoagulation, it may be feasible to pull the sheath back, leaving a wire in the aorta. Under careful hemodynamic and echocardiographic observation, this wire may be also pulled back 30 minutes later. In general, the need for closing device or open heart surgery is rare.²⁹

Systemic embolism. Another potential complication is embolism of thrombus or air. To avoid air embolism, catheters must be advanced and withdrawn slowly so as not to introduce air into the assembly. Sheaths must be aspirated with a syringe on a stopcock to the amount of their volume (e.g., an 8 Fr sheath contains 5 mL when filled) to remove any retained air each time a catheter is removed and prior to reintroduction. Thromboembolic complications can be avoided by flushing all sheaths and guidewire with heparinized saline and maintaining the ACT at longer than 300 seconds. In addition, a guidewire should not be left in the LA for more than 1 minute, especially if no systemic heparin has been administered. As noted earlier, administration of heparin before, rather than after, the atrial septal puncture can also help reduce thromboembolism. Importantly, the presence of an LA thrombus is an absolute contraindication for transseptal catheterization.^{18,19}

Occasionally, ST segment elevation in the inferior electrocardiogram (ECG) leads (with or without transient bradycardia or AV block) can occur following transseptal catheterization, potentially secondary to air embolism in coronary arteries, although a Bezold-Jarisch–like reflex mechanism can also be implicated.

Interatrial shunt. Iatrogenic atrial septal defects have been described in up to 20% to 30% of patients following transseptal atrial interventions, though about two thirds of these disappear with the first 12 months of follow-up.³⁰ Predictors of developing a persistent iatrogenic atrial septal defect include the size of the transseptal sheath, LA pressure, RV systolic pressure, and the presence of severe mitral or tricuspid regurgitation. The location of the transseptal puncture (fossa ovalis vs. inferior limbus), the use of RF-powered transseptal needles, and the anatomy of the interatrial septum (e.g., aneurysmal septum) have been suggested to predict a higher risk for the development of persistent iatrogenic atrial septal defects. The clinical significance of persistent iatrogenic atrial septal defects is not clear, but can potentially result in hemodynamically significant interatrial shunts in some patients.^{31–33}

Subxiphoid Epicardial Approach

Coronary veins can be used to perform epicardial mapping, but manipulation of the mapping catheter is limited by the anatomical distribution of these vessels. In contrast, the subxiphoid percutaneous approach to the epicardial space allows for unrestricted mapping of wide areas of the epicardial surfaces of the ventricles and most part of the epicardial atria surface. Percutaneous epicardial access has become an increasingly important tool for mapping and ablation of complex ventricular arrhythmias and for LA appendage exclusion using an epicardial ligation system like the Lariat device. More recently, investigators have applied the technique to manage supraventricular arrhythmias, including inappropriate sinus tachycardia, AT arising from the LA appendage, BTs, and AF.³⁴

Anatomical Considerations

The pericardium is a double-walled sac that contains the heart and the roots of the great arteries, SVC, and PVs. By separating the heart from its surroundings—the descending aorta, lungs, diaphragm, esophagus, trachea, and tracheobronchial lymph nodes—the pericardial space allows complete freedom of cardiac motion within this sac.³⁵

The pericardium consists of two sacs intimately connected with one another: an outer fibrous envelope (the fibrous pericardium) and an

inner serous sac (the serous pericardium). The fibrous pericardium (0.8 to 2.5 mm in thickness) consists of fibrous tissue and forms a flask-shaped bag, the neck of which is closed by its fusion with the adventitia of the great vessels, while its base is attached by loose fibroareolar tissue to the central tendon and to the muscular fibers of the left side of the diaphragm. The fibrous pericardium is also attached to the posterior sternal surface by superior and inferior sternopericardial ligaments. These attachments are essential to maintain the normal cardiac position in relation to the surrounding structures, to restrict the volume of the thin-walled cardiac chambers (RA and ventricle), and also to serve as direct protection against injuries.³⁶

The serous pericardium is a delicate membrane that lies within the fibrous pericardium and lines its walls; it is composed of two layers: the parietal pericardium and the visceral pericardium. The parietal pericardium is fused to and inseparable from the fibrous pericardium. On the other hand, the visceral pericardium, which is composed of a single layer of mesothelial cells, is part of the epicardium (i.e., the layer immediately outside of the myocardium) and covers the heart and the great vessels except for a small area on the posterior wall of the atria. The visceral layer extends to the beginning of the great vessels, and is reflected from the heart onto the parietal layer of the serous pericardium along the great vessels in tube-like extensions. This happens at two areas: where the aorta and pulmonary trunk leave the heart and where the SVC, IVC, and PVs enter the heart.^{34–37}

The pericardial cavity or sac is a continuous virtual space that lies between the parietal and visceral layers of serous pericardium. The heart invaginates the wall of the serous sac from above and behind, and practically obliterates its cavity, the space being merely a potential one. The pericardial sac normally contains 20 to 40 mL of clear fluid that occupies the virtual space between the two layers and serves as a lubricant.^{34,36}

The lateral surfaces of the heart are predominantly covered by the lungs, prohibiting a direct percutaneous access to the pericardial space. The anterior borders of the lungs extend vertically downward along the midsternal line. The right lung anterior border curves laterally and downward at the level of the sixth costal cartilage on the right side. On the left side, however, the anterior border of the lung diverges laterally at an earlier point (at the level of the fourth costal cartilage), forming the cardiac notch, and reaches the parasternal line at the fifth costal cartilage (about 1 inch from the sternal border) before turning medially and downward (as the lingula) to the sixth sternocostal junction (eFig. 4.6). Thus, the subxiphoid region offers a window for direct pericardial access without traversing the lungs. Nonetheless, even with the subxiphoid approach, a needle angulated too far in the lateral direction can potentially puncture the left lung and result in pneumothorax.^{38,39}

In the subxiphoid pericardial access approach, the needle traverses the skin, subcutaneous tissue, and rectus abdominis, and then travels above the dome of the diaphragm before arriving to the fibrous pericardium. In the vicinity of the path of the needle lie several important structures that can be vulnerable to damage, including the diaphragm and diaphragmatic vessels, left internal mammary artery, lung, left lobe of the liver, stomach, and transverse colon.

The diaphragm is a dome-shaped muscular structure that separates the thoracic cavity from the abdomen. The muscle fibers of the diaphragm emerge from the circumference of the inferior thoracic aperture and converge in a *central tendon*, which forms the crest of the dome. The pericardium rests on the central tendon, an almost flat area of the dome of the diaphragm (the cardiac plateau). Anteriorly, the muscle fibers of the diaphragm emerge from the xiphoid process and along the costal margin and arch back in a “parachute” shape to a maximum height equivalent to the xiphisternal junction at the midline. The left

hemidiaphragm conforms to the left lobe of the liver, the fundus of the stomach, the spleen, and the left kidney.³⁶ The left lobe of the liver is near the xiphoid process and can be particularly at risk in patients with hepatomegaly. Manual pressure over the right upper quadrant can help displace the liver and abdominal contents posteriorly away from the path of the needle.³⁸

The internal mammary (thoracic) artery arises from the subclavian artery and descends vertically 1 to 1.5 cm lateral to the sternal border, behind the first six costal cartilages, accompanied by the internal thoracic vein. After passing the sixth intercostal space, the internal mammary artery bifurcates into the superior epigastric artery (which continues downward into the abdominal wall) and the musculophrenic artery (which roughly follows the costal margin). The risk of puncturing the internal mammary artery is increased when the needle entry or trajectory is too lateral.

Technical Considerations

The subxiphoid approach procedure may be performed under conscious sedation, deep sedation with the support of an anesthesiologist, or general anesthesia. General anesthesia allows better control of respiratory motion, which can potentially reduce the chance of unintentional RV puncture, as well as better pain control, given the fact that epicardial RF ablation is usually associated with significant pain and discomfort. IV antibiotics are routinely administered within an hour prior to the procedure. Previous heparin administration should be reversed before pericardial access; this is accomplished by protamine infusion.

Advancing the needle. The pericardial space is accessed using a 17- or 18-gauge, blunt-tipped Tuohy needle (6 inches in length), which is also used to enter the epidural space when administering epidural anesthesia. The puncture is performed at the angle between the left border of the subxiphoid process and the lower left rib. A small incision on the skin at the puncture site helps reduce the resistance when introducing the pericardial access needle and enhance tactile feedback upon puncturing the fibrous pericardium. The needle is then introduced aiming toward the left midclavicle or the left shoulder and at a shallow angle (less than 20 degrees) in order to penetrate the skin and slide under the left rib cage, above and parallel to the dome of the diaphragm, while avoiding injury to diaphragmatic vessels and subdiaphragmatic organs. Occasionally, manual pressure over the epigastrium is required to push away the liver from the path of the needle.^{38,40}

Once over the dome of the diaphragm, the needle can be angled to a steeper degree (according to whether an anterior or posterior approach is preferred, see below) and advanced under fluoroscopic guidance (40-degree LAO view or, preferably, biplane RAO and LAO projections) until close to the cardiac silhouette. Directing the needle superiorly at a relatively shallow angle (passing just posterior to the sternum on a steep lateral fluoroscopy projection), aiming for the RV apex in the RAO projection, generally allows entry into the pericardial space anteriorly over the RV and facilitates access to the anterior aspect of the RV and LV. Directing the needle more posteriorly and toward the left shoulder allows it to enter the pericardium over the diaphragmatic portion of the heart, such that the sheath typically tracks along the posterior aspect of the LV, as observed in the LAO projection. The medial third of the RV is the preferred entry region because of the absence of major coronary vessels in this region.^{34,37}

Puncturing the parietal pericardium. As the needle approaches the cardiac silhouette on the LAO view, the needle stylet is removed and a 10-mL syringe containing a saline-contrast mixture is attached to the proximal port of the needle. In the 40-degree LAO view, injection of a minimal amount of contrast (less than 1 mL) can help assess the relation of the needle to the parietal pericardium. If the diaphragm has not been reached, the contrast will be seen in the subdiaphragmatic

area. On the other hand, pooling of contrast in the mediastinal space indicates that the needle has not reached the pericardial space. Puncture of the diaphragmatic attachments before accessing the pericardial space sometimes can be misinterpreted as the puncturing the parietal pericardium; in the former setting, contrast will pool in the mediastinum outside the parietal pericardium. A needle directed too laterally can result in patchy contrast in the pleural space.

When the needle arrives at the fibrous pericardium, the contrast is seen at the heart border and, with a slight advance of the needle, tenting of the pericardium can be observed. Care must be taken not to inject too much contrast that can potentially obscure the fluoroscopic image. If too much contrast is injected, the operator may consider waiting to allow the contrast to dissipate before attempting a second puncture.^{34,37}

Once tenting of the pericardium is seen, holding the needle still against the respiratory downward movement of the diaphragm or gentle forward pressure on the needle achieves entry into the pericardial space, and often one can feel a sensation of “give” as the needle penetrates the fibrotic parietal pericardial wall (i.e., release of resistance on the needle), coupled with the disappearance of tenting of the pericardium on the LAO fluoroscopic view (Fig. 4.13).^{37,41}

Needle entry into the pericardial space and contact with the myocardium can be suggested by tactile feedback, occurrence of ventricular ectopy, or observation of a current of injury from an alligator clip attached to the shaft of the needle. At this point, further advancement of the needle can result in ventricular puncture and should be avoided.^{34,37}

Confirming intrapericardial position of the needle. When the needle reaches the pericardial sac, aspiration without blood indicates that the needle has not entered the RV, and injected contrast will spread in a thin outline of the pericardium around the heart, restricted to its silhouette. At this point, a long soft J tip guidewire is advanced far enough so that it loops in the pericardial space. Confirmation that the wire is intrapericardial and has not been inadvertently inserted into a cardiac chamber is obtained by observing the course of the wire in multiple fluoroscopic projections confirming that it crosses multiple cardiac chambers and crosses the midline, hugging the edge of the cardiac silhouette in the 40-degree LAO view (circumferential to both the right and left heart), and without induction of PVCs (see Fig. 4.13). In the LAO fluoroscopic view, the guidewire will not cross the spine and outline the left cardiac border if it is in the RV. Observation in the RAO or anterior-posterior projection alone can be misleading, as a wire that enters the RV and passes into the RA or pulmonary artery can be misinterpreted as intrapericardial.^{42,43}

Inadvertent puncture of the RV is relatively common, but usually is not associated with serious consequences (less than 80 mL of pericardial bleeding) if only the needle or guidewire has entered the chamber. Therefore it is critical to recognize RV perforation before introducing the dilator and sheath. Crossing the RV myocardium by the needle can be indicated by aspiration of blood through the needle. In addition, RV perforation can be easily recognized by observation of the ejection of contrast injected through the needle into the pulmonary artery rather than forming a thin-walled contrast lining of the pericardium. If RV perforation could not be identified, and a guidewire is advanced through the needle, stimulation of the RV or RVOT by the wire typically induces PVCs or VT. In addition, the LAO fluoroscopy view will reveal a course of guidewire (usually passing through the RVOT into the pulmonary artery) different from that of the expected pericardial course described above. If the needle is confirmed to be within the RV, it should be slightly retracted (rather than completely withdrawn) and then a little more contrast can be injected until it is observed to layer within the pericardial space. At this point, the guidewire may be successfully advanced into the pericardial space, and the position reconfirmed

eFig. 4.6 Anatomic Relationship of the Heart and Surrounding Structures. (From Smith SE, Darling GE. Surface anatomy and surface landmarks for thoracic surgery: part II. *Thorac Surg Clin.* 2011;21:139–155.)

Fig. 4.13 Sequential Fluoroscopic Images of an Epicardial Access Procedure. A decapolar catheter is placed into the coronary sinus (CS) through a femoral venous approach. (A) Left anterior oblique (LAO) fluoroscopic view. Contrast injection through the Tuohy needle demonstrates tenting of the pericardium before puncture. (B and C) LAO view. As the needle is advanced, additional contrast is injected. Layering of contrast in the pericardial space confirms successful entry into the desired space. (D) LAO view. A guidewire is present in the pericardial space and traverses the transverse sinus. Note that the guidewire abuts the outer fluoroscopic border of the heart, thereby confirming its location in the proper space. (E) Right anterior oblique view. The guidewire remains within the transverse sinus. (F) LAO view of a different patient showing the position of the guidewire. (From Garikipati NV, Paruchuri V, Mittal S. How to learn epicardial intervention techniques in electrophysiology. *Card Electrophysiol Clin*. 2010;2:35–43.)

with the above criteria.^{37,42} If the guidewire is in the pericardial space, it should advance easily (in the absence of adhesions); if resistance is met, further efforts to advance the wire are discouraged as this will only result in distortion of the wire end, making it less useful for subsequent use.

Once an intrapericardial location of the guidewire is confirmed, the puncture needle is withdrawn and gradual dilatation of the puncture site is performed over the guidewire, followed by insertion of the desired sheath. Serial dilators are used to dilate the epicardial access route and then the epicardial sheath is advanced into the pericardial space. Dilators should be advanced carefully to avoid compression of the RV or kinking of the guidewire. Using a guidewire with a very soft tip but a relatively stiff proximal segment can help support advancing the dilators and sheath through the tough fibrous pericardium. Before removing the dilator out of the sheath, the sheath must be pushed against the chest to ensure that the tip of the sheath is placed well inside the pericardial sac to prevent loss of access. Although using a standard 15 cm, 8 Fr sheath may suffice, the use of longer sheaths (e.g., Agilis, St. Jude Medical, St. Paul, MN, United States) should be considered, especially in patients with a larger thoracic anteroposterior dimension.³⁷

It is preferred to maintain the option for a second pericardial access. This can provide access for a second pericardial sheath when needed (e.g., for a balloon to protect the phrenic nerve), but also can become important in the setting of inadvertent loss of the initial epicardial access or when repeated aspiration of pericardial fluid becomes necessary during the epicardial procedure. A second guidewire can be advanced through the pericardial sheath; the sheath is then removed, leaving two guidewires inside the pericardial space. Subsequently, the sheath desired for introducing the catheter is advanced over one guidewire, while the second guidewire is secured in place or a second sheath is introduced when necessary.

Before introducing the mapping-ablation catheter, the pericardial sheath must be aspirated to check for bleeding. When bleeding is under control, the mapping-ablation catheter can be introduced. Once it is inside the pericardial sac, the catheter can usually be easily moved, allowing exploration of the entire epicardial surface. Adhesions from prior pericardial entries (surgical, prior catheter ablation procedures) or idiopathic pericarditis (sometimes subclinical) can limit access to all portions of the epicardium.

EpiAccess Smart Needle. Recently, a novel epicardial access needle with an integrated needle tip pressure transducer has been developed (EpiAccess Smart Needle, EpiEP, New Haven, CT, United States). The system includes a proprietary needle (similar to the Tuohy needle in shape and size) with a fiber optic pressure sensor mounted permanently at the distal tip. The EpiAccess device provides real-time pressure frequency data designed to detect the extrapericardial, pericardial, and ventricular transitions to provide immediate adjunctive confirmation of the needle tip location during its introduction into the pericardial space.⁴⁴

The needle tip pressure frequency signal (along with an arterial line signal) is displayed as a raw waveform on the graphical user interface, and a proprietary algorithm conducts a beat-to-beat analysis of the needle tip pressure frequency and graphs the pulsatile pattern within the needle tip pressure signal. The arterial pressure signal is used by the system as a reference to compare with the pulsed pressure signal pattern of the needle tip. Consistent pulsatile pressure is also displayed in a bar graph format to provide an additional visual notification that the needle has or is about to enter the pericardial sac (Fig. 4.14).

As the needle is advanced towards the heart, no pressure is detected from the entry site in the epigastrium to the parietal pericardium. Once the needle is in contact with the parietal pericardium, a transition signal is observed, which correlates with tenting of the fibrous and parietal pericardium on fluoroscopy. Upon entering the pericardial space, the pressure monitor displays a real-time amplitude shift in frequency and a pressure signal ranging from 15 to 25 mm Hg (see Fig. 4.14). When the needle is touching the RV wall or is inside the RV cavity, the needle tip tracing displays a significantly higher pressure signal oscillating between 120 and 220 mm Hg.

“Needle-in-needle” technique. The use of a 21-gauge micropuncture needle (instead of the 18-gauge Tuohy needle) has been suggested for epicardial access to help reduce the risk of pericardial bleeding. Inadvertent cardiac or vascular puncture with the finer needle is less likely to result in significant bleeding, as compared to the larger Tuohy needle. However, it is often challenging to direct the thin micropuncture needle under the sternum because it tends to flex over the course of insertion. The “needle-in-needle” technique utilizes a short (7-cm) 18-gauge stiff needle to navigate the subcutaneous tissue and provide the proximal stability and support necessary to guide the longer (20-cm) micropuncture needle through the subcutaneous tissue and gain entry into the pericardial space (telescoping approach).^{45,46}

The “needle-in-needle” technique replaces the Tuohy needle with two needles: an 18-gauge, 7-cm Cook needle and a 21-gauge micropuncture or a long spinal (21-gauge, 20-cm) needle. Initially, the 18-gauge short needle is advanced via the subxiphoid puncture site (in a fashion similar to that described using the Tuohy needle). Once the tip of the needle arrives under the rib cage, and well before it reaches the cardiac silhouette, the micropuncture needle is inserted through the 18-gauge needle. The 21-gauge needle alone is used to puncture the parietal

pericardium and enter the pericardial space (with the aid of contrast, fluoroscopy, and tactile sensation, as described for the Tuohy needle technique). Once an intrapericardial location of the needle tip is confirmed, an 0.018-inch floppy-tip guidewire is advanced through the 21-gauge needle into the pericardial space. Once an intrapericardial location of the wire is confirmed (as described above), both needles are removed and a micropuncture dilator is advanced into the pericardial space over the guidewire and then exchanged for a 6 Fr dilator. The 0.018-inch guidewire is then exchanged for a floppy-tip 0.35-inch guidewire.^{45,46}

The “needle-in-needle” technique was found to offer several advantages over the conventional Tuohy needle technique. The micropuncture needle is able to penetrate tough fibrous pericardium and with less resistance, requiring less force and torque. This helps a more controlled needle entry to the pericardial space and avoids an “overshoot” of the needle after crossing the parietal pericardium. Even when the RV wall is inadvertently punctured, the likelihood of auto-seal of the puncture site is higher with the small-caliber needle, which translates into lesser risk of significant pericardial bleeding and subsequent need of surgical repair.^{45,46}

A disadvantage of this technique is the limited tactile feedback transmitted by the micropuncture needle upon crossing the parietal pericardium. In addition, the 0.018-inch guidewire may be difficult to visualize with low-quality fluoroscopy.^{45,46}

Anterior versus posterior approach for epicardial access. Depending on the anatomical region of interest, either an anterior or a posterior (inferior) approach to pericardial puncture may be chosen (Fig. 4.15). The anterior or posterior approach allows access to the anterior surface of the ventricles and LA appendage, and also allows access to the posterior and inferior regions of the heart (by looping the ablation catheter around the IV). On the other hand, the posterior approach allows easier access to the inferior ventricular walls and posterior LA walls. In addition, the posterior approach may be preferred in patients with prior cardiac surgery, since the pericardial adhesions are typically more extensive anteriorly, limiting the anterior approach.

For the anterior approach, the pericardial needle is advanced at a shallow angle (20 to 30 degrees in the LAO view), and closer to the midline, which allows entry to the pericardial space anteriorly over the RV. In contrast, for the posterior approach, once the needle passes over the dome of the diaphragm, it is directed more posteriorly at a steeper angle (greater than 45 degrees), aiming toward the basal portion of the heart (marked by the CS catheter in the LAO view), and slightly more leftward (to minimize the risk of injury to the posterior descending artery), which allows entry to the pericardial space under the inferior aspect of the ventricles.⁴⁷

When the curved-tip Tuohy needle is used, the needle bevel is pointed away from the myocardium (upward during the anterior approach and downward during the posterior approach) to minimize the risk of cardiac perforation and point the guidewire in the desired direction.³⁷

Fig. 4.14 The EpiAccess Needle. (A) The EpiAccess needle is depicted at the entry site in the subxiphoid area. Note that this needle is connected to a cable in order to transmit the pressure data into a screen monitor. (B) EpiAccess needle with a distal tip fiber optic sensor. (C and D) EpiAccess monitor screen. Arterial blood pressure and needle tip pressure tracings are displayed in the monitor of the EpiAccess System. (C) EpiAccess waveform showing transition from the extrapericardial to the pericardial space. (D) EpiAccess waveform showing transition from the myocardium or right ventricle to the pericardial space. Note the higher amplitude signals once the needle tip is against the right ventricular (RV) free wall. The needle is gently retracted into the pericardial space with signals ranging from 15 to 25 mm Hg. (Modified from Di Biase L, Burkhardt JD, Reddy V, et al. Initial international multicenter human experience with a novel epicardial access needle embedded with a real time pressure/frequency monitoring to facilitate epicardial access: feasibility and safety. *Heart Rhythm*. 2017;14:981–988.)

Fig. 4.15 Anterior Versus Posterior Approach for Epicardial Access. Diagrammatic representation of needle entry utilized in inferior (A) and anterior (B) approach epicardial access, respectively. Note the “bevel-out” needle tip position. (From Killu AM, Wan SH, Munger TM, et al. Pericardial effusion following drain removal after percutaneous epicardial access for an electrophysiology procedure. *Pacing Clin Electrophysiol.* 2015;38:383–390.)

Generally, the anterior approach is considered safer than the posterior approach, and is preferred, whenever possible. The shallow angle of the needle trajectory used for the anterior approach directs the needle above and parallel to the dome of the diaphragm directly toward the fibrous pericardium, obviating injury to diaphragmatic vessels and subdiaphragmatic organs. Conversely, a steeply angled needle (as used for the inferior approach) is more likely to pass through the diaphragm and can potentially puncture subdiaphragmatic structures (vessels, liver, colon). Furthermore, with the posterior approach, there is potential risk, although small, of damage to the posterior descending artery; this risk can be mitigated by directing the needle away from the septum.³⁸

Pericardial adhesions. Attempted epicardial access fails in approximately 10% of patients, primarily due to the presence of pericardial adhesions (e.g., following cardiac surgery or pericarditis). Even when epicardial access is possible, the presence of pericardial adhesions can significantly limit catheter maneuverability within the pericardial space.⁴²

In postsurgical patients, the adhesions are mostly concentrated in the anterior portion of the heart (the area where the pericardial sac was opened during sternotomy); therefore the puncture must be directed toward the diaphragmatic area (posterior approach). In this setting, contrast pooling along the inferior wall (instead of spreading around the cardiac silhouette) and restricted intrapericardial maneuverability of the guidewire often are observed, indicating the presence of pericardial adhesions. Conversely, adhesions can be more diffuse in postpericarditis patients, severely limiting percutaneous access to the pericardium.^{37,42,48}

In patients with pericardial adhesions, the curve of the deflected ablation catheter can be used to gently disrupt the adhesions; however, care must be taken to avoid cardiac perforation with the catheter tip in these cases. A hybrid procedure involving surgical access with a sub-xiphoid pericardial window or a limited anterior or lateral thoracotomy combined with manual dissection and lysis of the adhesions can facilitate access to the epicardial region of interest. However, access to other areas may still be limited.^{47–49}

Complications of Pericardial Access

Pericardial bleeding. Pericardial bleeding related to the epicardial access procedure is most commonly related to myocardial injury. The coronary arteries are covered by epicardial fat along the AV groove and the interventricular septum, located away from the typical path of the

access needle and therefore are less vulnerable to injury. Occasionally, disruption of epicardial fat can result in limited bleeding.

The anterior wall of the RV is the cardiac structure most vulnerable to perforation during the anterior approach. RV puncture is not rare, and usually occurs when the needle inadvertently overshoots into the RV myocardium after crossing the tough fibrous pericardium. RV puncture is usually benign if only the needle or guidewire has entered the chamber in a patient who is not anticoagulated. When the RV is inadvertently entered with the needle (indicated by aspiration of blood or contrast injection passing to the pulmonary artery), the needle can be withdrawn slightly (reentering the pericardial space after exiting the ventricle); contrast injection can then show silhouetting of the heart, and at that point the guidewire is advanced into the pericardial space. The small hole in the RV generally seals without incident. If the dilator and sheath have been passed into the RV, the larger hole may require surgical repair. In this setting, it may be preferable to leave the sheath in the RV and obtain a pericardial access and carry out the intended epicardial procedure. After completion of the procedure, the RV sheath may be removed when the surgical team is prepared to intervene immediately if required.^{38,42,46} Alternatively, the surgical consultant may prefer a limited thoracotomy or even sternotomy prior to sheath removal to ensure control of bleeding.

The use of the “needle-in-needle” technique can help reduce the risk of significant bleeding in the setting of inadvertent RV puncture.^{45,46} In addition, when the curved-tip Tuohy needle is used, directing the needle bevel away from the myocardium can help minimize the risk of cardiac perforation.³⁷

Approximately 10% to 20% of patients experience pericardial bleeding, particularly if inadvertent RV puncture has occurred. Bleeding is managed by frequent aspiration from the pericardial access sheath. Continued bleeding may require urgent surgical intervention. It is not uncommon to aspirate 10 to 30 mL of bloody drainage from the pericardial sheath early in the procedure. At this point, anticoagulation should not have been administered; therefore any bleeding should be self-limited and is generally considered a minor complication because it is not necessary to interrupt the procedure. Systemic anticoagulation with IV heparin is started when subsequent LV endocardial mapping is desired, but only after verifying the absence of continued pericardial bleeding.³⁷

There is concern that abrasion or laceration of pericardial structures can occur by the edges of a stiff sheath if the sheath is left in the pericardium without a catheter protruding from the lumen. Therefore it is recommended not to leave a large sheath in the pericardial space without a catheter in place. Also, it is important to lead with a wire or ablation catheter before advancing or moving the curl of the sheath to avoid damaging epicardial structures.⁴²

Intraabdominal bleeding. Infrequently (0.5% in one case series), intraabdominal bleeding can occur during the epicardial access procedure. Hemoperitoneum secondary to injury to the subdiaphragmatic vessels (e.g., epigastric artery) or abdominal viscera (liver and colon) can occur when the angle of the needle is too steep (during the posterior approach to pericardial access) or if the subxiphoid entry site is too caudal. The risk is higher in obese patients and in the presence of hepatomegaly, bowel distension, or left diaphragmatic paralysis.^{37,42,50} Also, the presence of a large hiatal hernia can predispose to inadvertent perforation (and subsequent mediastinal infections) during cannulation attempts.

Although perforation of the liver and intrahepatic bleeding can be well tolerated, more severe degrees of abdominal bleeding can result in acute hemodynamic decompensation and refractory hypotension and can necessitate immediate surgical intervention. Importantly, significant intraabdominal bleeding can develop only upon sheath withdrawal (and removal of the tamponading effect of the sheath) after the completion of the procedure.^{37,42,50}

Recognition of this complication can be difficult and requires a high index of suspicion. Abdominal pain (in unanesthetized patients), rebound tenderness, progressive hypotension in the absence of a pericardial effusion, and unexplained decrease in hemoglobin should prompt evaluation with abdominal ultrasound or (in hemodynamically stable patients) computed tomography (CT) imaging.

Adequate palpation of the xiphoid process, manual pressure over the epigastrium to push the liver away from the path of the needle, using a shallow needle angle, and avoiding sideways movements of the needle can help prevent injury to subdiaphragmatic structures. Also, avoiding general anesthesia at the time of epicardial access can help early recognition of this complications as it can manifest as abdominal pain.^{37,42,50}

Pneumopericardium. Air can be introduced into the pericardial space during the exchange of sheaths and catheters. Although pericardial air rarely causes cardiac tamponade, it can increase the transthoracic defibrillation threshold. Air in the pericardial space tends to stay around the cardiac apex (which is located most anteriorly located in the supine position) and is easily detected on fluoroscopy. Once detected, pericardial air should be evacuated, especially before the induction of ventricular arrhythmias that may require electrical cardioversion.³⁷ Careful sheath management to prevent air aspiration is important.⁴² On the other hand, air or an air-saline mixture may be introduced into the pericardial space intentionally (in a controlled manner) to physically displace a phrenic nerve from an epicardial ablation target site.

SIGNAL ACQUISITION AND PROCESSING

Cardiac electrograms are generated by the potential (voltage) differences recorded at two electrodes during the cardiac cycle. All clinical electrogram recordings are differential recordings from one source that is connected to the anodal (positive) input of the recording amplifier and a second source that is connected to the cathodal (negative) input.⁵¹

Whereas the surface ECG records a summation of the electrical activity of the entire heart, intracardiac electrograms recorded by the electrode catheter represent only the electrical activity (phase 0 of the action potential) of the local cardiac tissue in the immediate vicinity of the catheter's electrodes.

Unipolar electrograms represent the potential difference between the electrode in close association with cardiac tissue (the exploring electrode) and a distant *indifferent* (reference) electrode which is placed at a distance from the heart (so that the indifferent electrode has little or no cardiac signal). In practice, the Wilson central terminal is used to approximate the indifferent electrode. The precordial ECG leads, for example, are unipolar recordings that use an indifferent electrode created by connecting the arms and left leg electrodes through high-impedance resistors. Bipolar electrograms represent the potential difference between two electrodes and are calculated as the algebraic difference between the two unipolar electrograms at the two sites (using the same reference electrode).⁵²

The electrode is an electrical conductor which is used to make contact with the heart and convert ionic currents into electrical currents that can be detected by electronic devices. These currents are typically very small and, hence, must be processed and displayed in an easily understandable manner. This involves amplification and filtering of the signals.

Analog Versus Digital Recordings

Intracardiac electrograms are recorded with amplifiers that have high-input impedances (greater than 1010 Ω), to reduce unwanted electrical interference and ensure high-quality recordings. Analog recording systems directly amplify the potential from the recording electrodes, plot the potential on a display oscilloscope, and write it to recording paper or store it on magnetic tape.⁵¹

Analog systems have largely been replaced by digital recording systems that use an analog to digital (A/D) converter that converts the amplitude of the potential recorded at each point in time to a number that is stored. The quality of digital data is influenced by the sampling frequency and precision of the amplitude measurement. The most common digital recording systems sample the signal approximately every 1 millisecond (i.e., 1000 Hz), which is generally adequate for practical purposes of activation mapping. However, higher sampling frequencies can be required for high-quality recording of high-frequency, rapid potentials that can originate from the Purkinje system or areas of infarction. The faster sampling places greater demands on the computer processor and increases the size of the stored data files.⁵¹

Signal Amplification

The amplitude of intracardiac electrograms is usually small, ranging from 25 μV (recorded from scarred myocardium) to 5 mV (from a surface ECG lead). Therefore signal amplification (voltage gain) is necessary and is achieved by electronic amplifiers (voltage amplifiers), which can amplify recorded signals (up to 10,000 times) to a large enough voltage to be displayed and easily visualized. However, the recorded signal is often contaminated with noise, and signal amplification can also amplify the noise. Therefore signal filtering is required. To further enhance the signal-to-noise ratio, a type of electronic amplifier (differential amplifier or instrumentation amplifier) amplifies the difference between two voltages while rejecting any signal common to both inputs.⁵³ Of note, excessive electrogram amplification can result in electrogram saturation and signal cutting.⁵⁴

Signal Clipping

Electrogram clipping is useful when the intracardiac electrogram of interest (e.g., His potential) is small relative to the size of surrounding electrograms (e.g., ventricular signal), and the gain must be markedly increased to produce a measurable deflection. In this setting, clipping the signals can help eliminate the highly amplified surrounding signals (that do not need to be visualized to their full extent) and allow focusing on the deflection of interest (Fig. 4.16). It is important to recognize, however, that clipping eliminates the ability to determine the amplitude

Fig. 4.16 Effect of Electronic Clipping on Recordings. The same two complexes are shown in both panels. *Left*, Both His and coronary sinus (CS) recordings are electronically attenuated (clipped) to reduce excursions on the display. The CS atrial and ventricular signals appear to have equal amplitude, and the ventricular electrogram in the His recording is small. *Right*, Without clipping, the true signal amplitudes are seen, showing a very large ventricular signal in the His recording and a larger atrial than ventricular signal in the CS recording. *Abl_{dist}*, Distal ablation; *Abl_{uni}*, unipolar ablation; *CS_{dist}*, distal coronary sinus; *His_{dist}*, distal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

and timing of the intrinsic deflection (local timing) of the signals being clipped.⁵⁴

Signal Filtering

Filtering enhances certain portions of the frequency spectrum while rejecting unwanted portions of the spectrum. The range of frequencies not filtered out is frequently called the band pass. The high-pass filter allows frequencies higher than a certain limit to remain in the signal (i.e., it filters out lower frequencies), while the low-pass filter allows frequencies lower than a certain limit to remain in the signal.⁵³

Surface ECG signals and intracardiac electrograms contain different frequencies and therefore require different filtering parameters. Bipolar intracardiac electrograms are usually filtered at 30 to 500 Hz, whereas unipolar electrograms are filtered at 0.05 to 500 Hz.

Diagnostic-quality surface ECG signals are usually filtered at 0.05 to 100.0 Hz. Although the bulk of the energy is in the 0.1- to 20.0-Hz range, the lower frequency cutoff of 0.05 Hz is a better reproduction of the ST segments (but at the expense of more baseline drift) and the upper cutoff frequency of 100 Hz is a better reproduction of high-frequency components in the P-QRS (but at the expense of increased susceptibility to interference at the power-line frequency of 50 to 60 Hz). An upper cutoff frequency of 100 Hz enables detailed analysis of the morphology of the P wave and QRS complex (which is of importance

during arrhythmia mapping) as well as identification of high-frequency fragmented P-QRS components (e.g., Epsilon waves). Because of interference from alternating current (AC), muscle twitches, and similar relatively high-frequency interference, it is sometimes necessary to record the surface ECG over a lower frequency range or to use notch filters. An optional notch filter is provided at 50/60 Hz to further reject line frequency interference. Monitor-quality ECGs are usually filtered at 0.5 to 40 Hz.^{53,54}

High-Pass Filtering

High-pass filtering allows signals faster than a specified frequency (the cutoff frequency or corner frequency) to be transmitted unchanged while rejecting or significantly attenuating the amplitude of signals slower than the cutoff frequency. If intracardiac recordings were not filtered, the signal would wander up and down as this potential fluctuates with respiration, catheter movement, and variable catheter contact.⁵³

For bipolar electrograms, high-pass filters with corner frequencies between 10 and 50 Hz are commonly used for rejection of baseline drift. Filtering can distort the electrogram morphology and reduce its amplitude. The bipolar signal becomes more complex, and additional peaks are introduced. In general, high-pass filtering can be viewed as differentiating the signal, so that the height of the signal is proportional to the rate of change of the signal, rather than only the amplitude.⁵²

Unipolar signals are commonly filtered at 0.05 to 0.5 Hz to remove baseline drift and DC voltages (which, by definition, have a frequency of 0 Hz). Filtering at higher corner frequencies (e.g., 30 Hz) alters the morphology of the signal so that the morphology of the unipolar signal is no longer an indication of the direction of wavefront propagation and the presence or absence of a QS complex cannot be used to infer proximity to the site of earliest activation. However, filtering the unipolar signal does not affect its usefulness as a measure of the local activation time. During mapping of areas with infarcts or scars, where local electrograms can have very low amplitude and can be masked by larger far-field signals, high-pass filtering of a unipolar signal (at 30 Hz) can help reduce the far-field signal and improve detection of the lower amplitude local signals.⁵²

Low-Pass Filtering

Low-pass filters attenuate frequencies that are faster than the specified corner frequency (usually 250 to 500 Hz). This approach is useful for reducing high-frequency noise without substantially affecting electrograms recorded with clinical systems where most of the signal content is lower than 300 Hz.⁵² A reduction of the low-pass filter to less than 250 Hz is not recommended because of attenuation of high-frequency electrogram contents that are essential for near-field signals recorded from the HB, HPS, and PVs, as well as scar-containing slow-conduction sites with fractionated high-frequency electrograms.^{53,54}

Band-Pass Filtering

Defining a band of frequencies to record, such as setting the high-pass filter to 30 Hz and the low-pass filter to 300 Hz, defines a band of frequencies from 30 to 300 Hz that are not attenuated (i.e., band-pass filtering).

Notch Filtering

A notch filter is a special case of band-pass filtering, with specific attenuation of frequencies at 50 or 60 Hz to reduce electrical noise introduced by the frequency of common AC current. Importantly, notch filtering can significantly attenuate certain local intracardiac signals, such as near-field PV potentials or rapidly varying fractionated potentials.⁵³ In addition, notch filtering can introduce “ringing” to sharp simple bipolar signals, making them appear fractionated. This is a particular concern when targeting fractionated potentials during VT and AF.¹

INTRACARDIAC ELECTROGRAMS

Recorded intracardiac electrograms can provide three important pieces of information: (1) the local activation time (i.e., the time of activation of the myocardium immediately adjacent to the recording electrode relative to a reference), (2) the direction of propagation of electrical activation within the field of view of the recording electrode, and (3) the complexity of myocardial activation within the field of view of the recording electrode.

Significant differences exist between unipolar and bipolar recording in terms of spatial resolution (i.e., ability to locate the discrete area of excited tissue generating the recorded potentials), temporal resolution (i.e., ability to identify the local activation time which coincides best with the arrival of the depolarization wavefront), and directionality (i.e., ability to provide information regarding the direction and the origin of wavefronts). Those differences can be utilized to assist in mapping by simultaneously recording bipolar and unipolar signals from the mapping catheter.⁵¹ Although bipolar recordings provide sufficient information for most mapping purposes in clinical EP laboratories, simultaneous unipolar recordings can provide an indication of the

direction of wavefront propagation and a more precise measure of the timing of local activation.

Unipolar Recordings

A unipolar electrogram is the voltage difference recorded between an intracardiac electrode in close association with cardiac tissue (the exploring electrode) and a distant *indifferent* (reference) electrode which is placed at a distance from the heart (so that the indifferent electrode has little or no cardiac signal), such as at the Wilson central terminal or an electrode positioned in the IVC. The amplitude of the unipolar signal is directly proportional to the area of the wavefront of depolarization and inversely proportional to the square of its distance from the exploring electrode. Poor electrode contact manifests as a slow (low rate-of-change) signal instead of the expected rapid positive-to-negative polarity change.^{52,55}

Spatial Resolution

Unipolar recordings have poor signal-to-noise ratio and contain substantial far-field signal generated by depolarization of tissue remote from the recording electrode because the unipolar electrode records a potential difference between widely spaced electrodes. Therefore distant activity can be difficult to separate from local activity. This is especially true when recording from areas of scarred myocardium, where the fractionated ventricular potentials are ubiquitous and it is often impossible to select a rapid negative dV/dt when the entire QS potential is slowly inscribed—that is, cavity potential.

Noise can be reduced by using an indifferent electrode in the IVC instead of the Wilson central terminal. In addition, filtering the unipolar electrograms can help eliminate far-field signals; however, the filtered unipolar recordings lose the ability to provide directional information. The unipolar electrograms are generally unfiltered (0.05 to 300 Hz or more). When an abnormal tissue (scars or infarct areas) is studied, where local electrograms can have very low amplitude and can be masked by larger far-field signals, the unipolar recordings can be filtered at settings comparable to those of bipolar electrograms (10 to 40 to 300 Hz or more).

Temporal Resolution

Unipolar recordings provide a more precise measure of the timing of local activation than bipolar recordings. This is true for filtered and unfiltered unipolar electrograms.⁵¹ By convention, the exploring electrode in contact with the cardiac tissue is connected to the positive input of the recording amplifier. In this configuration, a wavefront propagating toward the exploring electrode generates a positive deflection, whereas a wavefront traveling away from the electrode generates a negative deflection. Thus, an approaching wavefront creates a positive deflection that quickly reverses itself as the wavefront travels past the electrode, thus generating an RS complex. The transition from positive to negative occurs when the wavefront is immediately beneath the exploring electrode and is marked by the steepest negative slope of the signal. In normal homogeneous tissue, the maximum negative slope (dV/dt) of the signal coincides with the arrival of the depolarization wavefront directly beneath the electrode because the maximal negative dV/dt corresponds to the maximum sodium (Na⁺) channel conductance (Fig. 4.17). This is true for filtered and unfiltered unipolar electrograms.⁵⁶

Directionality

The morphology of the unfiltered unipolar electrogram provides information about the direction of impulse propagation (and therefore its origin); positive deflections (R waves) indicate propagation towards the recording electrode, and negative deflections (S waves) indicate

Unipolar recordings: local vs. remote events

Fig. 4.17 Unipolar and Bipolar Recordings. Two complexes from different sites are shown in a patient with Wolff-Parkinson-White syndrome. The dashed line denotes onset of the delta wave. In site A, the unfiltered unipolar recording shows a somewhat blunted “QS” complex and small atrial component, but the filtered (30- to 300-Hz) bipolar signal shows a very large atrial signal and very small ventricular signal (arrow), suggesting a poor choice for ablation site. Site B shows a sharper “QS” in the unipolar signal, with a larger ventricular than atrial electrogram, and the initial nadir of bipolar recording coincides with the maximal negative dV/dt of the unipolar recording. Ablation at this site was successful. *Abl_{dist}*, Distal ablation; *Abl_{uni}*, unipolar ablation; *CS_{dist}*, distal coronary sinus; *His_{dist}*, distal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

propagation away from the electrode. A biphasic electrogram (positive then negative, RS complex) indicates a wavefront of depolarization traveling past the electrode, representing the approach and recession of the activation wavefront. If the wavefront originates immediately below the exploring electrode, it spreads away from the electrode in all directions simultaneously, producing a negative deflection (QS) with no R wave. Importantly, a QS electrogram configuration has a low spatial resolution and relatively low specificity, being attainable in an area of more than 1 cm in diameter from the real site of origin of the arrhythmia.^{52,57}

As noted, filtering the unipolar electrogram at higher corner frequencies (e.g., 30 Hz) alters its morphology so that it no longer indicates the direction of wavefront propagation and, then, the presence or absence of a QS complex cannot be used to infer proximity to the site of earliest activation.

Bipolar Recordings

Bipolar recordings are obtained by connecting two electrodes that are exploring the area of interest to the recording amplifier. At each point in time, the potential generated is the sum of the potential from the positive input and the potential at the negative input. The potential at the negative input is inverted; this is subtracted from the potential at the positive input so that the final recording is the difference between the two.⁵¹

Spatial Resolution

Bipolar recordings provide an improved signal-to-noise ratio. In addition, high-frequency components are more accurately seen, which facilitates identification of local depolarization, especially in abnormal areas of infarction or scar.

Unlike unipolar recordings, bipolar electrodes with short interelectrode distances are relatively unaffected by far-field events and mainly reflect the local electrical activity produced by the area of tissue in contact with and between the two electrodes. The bipolar electrogram is simply the difference between the two unipolar electrograms recorded at the two poles. Because the far-field signal is similar at each instant in time, it is largely subtracted out, thus leaving the local signal. Therefore compared with unipolar recordings, bipolar recordings provide an improved signal-to-noise ratio, and high-frequency components are more accurately seen. This allows more accurate visualization of high frequency components of the electrogram. As the distance from the recording site increases, amplitude and frequency of the recorded signal decrease depending on the interelectrode distance.

To acquire true local electrical activity, a bipolar electrogram with an interelectrode distance of less than 1 cm is desirable. Smaller interelectrode distances record increasingly local events (as opposed to far-field). Elimination of far-field noise is usually accomplished by filtering the intracardiac electrograms, typically at 30 to 500 Hz.

Temporal Resolution

Algorithms for detecting local activation time from bipolar electrograms have been more problematic, partly because of generation of the bipolar electrogram by two spatially separated recording poles. Multiple methods were proposed. In a homogeneous sheet of tissue, the initial peak of a filtered (30 to 300 Hz) bipolar signal coincide with depolarization beneath the recording electrode and appears to correlate most consistently with local activation time, corresponding to the maximal negative dV/dt of the unipolar recording (see Fig. 4.17). However, in the setting of complex multicomponent bipolar electrograms, such as those with marked fractionation and prolonged duration seen in regions with complex conduction patterns (e.g., in regions of slow conduction in macroreentrant AT or VT), determination of local activation time becomes challenging, and the decision about which activation time is most appropriate needs to be made in the context of the particular rhythm being mapped.^{51,58}

Directionality

In contrast to unipolar electrograms, the direction of wavefront propagation cannot be reliably inferred from the morphology of a single bipolar signal (direction can, however, be inferred from the relative timing of two adjacent bipolar recordings).

Several factors can affect bipolar electrogram morphology and amplitude, including: (1) the orientation of the bipolar recording axis to the direction of propagation of the activation wavefront; (2) electrode size; (3) interelectrode distance; (4) electrode-tissue contact (i.e., the distance between the source of the potential and the recording electrode); (5) conduction velocity (the greater the velocity, the higher the peak amplitude of the filtered bipolar electrogram); and (6) the mass of the activated tissue. A wavefront that is propagating in the direction exactly perpendicular to the axis of the recording dipole produces no difference in potential between the electrodes and hence no signal is recorded.

Nevertheless, a change in morphology can provide important clues about the activation pattern of the propagating wavefront.

Timing of Local Events

As noted, with an unfiltered unipolar electrogram, a wavefront of depolarization that is propagating toward the exploring electrode generates a positive deflection (an R wave). As the wavefront reaches the electrode and propagates away, the deflection sweeps steeply negative. This rapid reversal constitutes the intrinsic deflection of the electrogram and represents the timing of the most local event (i.e., at the site of the electrode). The maximum downslope (dV/dt) of the unipolar electrogram coincides with the arrival of the depolarization wavefront directly beneath

the electrode and is now considered the most accurate marker of local tissue activation (see Fig. 4.17).^{52,55}

Filtering the unipolar signal does not affect its usefulness as a measure of the local activation time. The slew rate or dV/dt of the filtered electrogram is so rapid in normal heart tissue that the difference between the peak and the nadir of the deflection is 5 milliseconds or less. Identification of the local event is therefore easy with filtered or unfiltered electrograms in normal tissue. On the other hand, diseased myocardium can conduct very slowly with fractionated electrograms, and this makes local events harder to identify.

To acquire true local electrical activity, a bipolar electrogram with an interelectrode distance of less than 1 cm is preferable. Smaller interelectrode distances record increasingly local events. In normal homogeneous tissue, the initial peak of a filtered (30 to 300 Hz or more) bipolar recording coincides with depolarization beneath the recording electrode and corresponds to the maximal negative dV/dt of the unipolar recording (see Fig. 4.17). However, in the setting of complex multicomponent bipolar electrograms, such as those with marked fractionation and prolonged duration seen in regions with complex conduction patterns, determination of local activation time becomes problematic.

Choices of Surface and Intracardiac Signals

Baseline recordings obtained during a typical EP study include several surface ECG leads and several intracardiac electrograms, all of which are recorded simultaneously. Timing of events with respect to onset of the QRS complex or P wave on the surface ECG is often important during the EP study, but it is cumbersome to display all 12 leads of the regular surface ECG. It is more common to use leads I, II, III, V1, and V6, which provide most of the information required to determine the frontal plane axis, presence and type of intraventricular conduction abnormalities, and P wave morphology.

Intracardiac leads can be placed strategically at various locations within the cardiac chambers to record local events in the region of the lead. A classic display would include three to five surface ECG leads, high RA recording, HB recording, CS recording, and RV apex recording (Fig. 4.18). Depending on the type of study and information sought, stimulation and recording from other sites can be appropriate and can include RB recording, LV recording, transseptal LA recording, and atrial and ventricular mapping catheter tracings for EP mapping and ablation.⁵²

The intracardiac electrograms are generally displayed in the order of normal cardiac activation. The first intracardiac tracing is a recording from the high RA close to the sinus node. The next intracardiac tracing is the HB recording, obtained from a catheter positioned at the HB, which shows low septal RA, HB, and high septal RV depolarizations. One to nine recordings may be obtained from the CS, which reflects LA activation, followed by a recording from the RV catheter (see Fig. 4.18).

Right Atrial Electrogram

Depending on the exact location of the RA catheter, the high RA electrogram typically shows a local sharp, large atrial electrogram and a smaller, far-field ventricular electrogram. The catheter is usually positioned in the RA appendage because of stability and reproducibility. The recorded atrial electrogram is earlier in the P wave when the catheter is positioned close to the sinus node. Recordings from this site also help determine the direction of atrial activation (e.g., high-low versus low-high, and right-left versus left-right). Pacing at this position allows evaluation of sinus node function and AV conduction, as well as the induction of supraventricular, and occasionally ventricular, arrhythmias.

Fig. 4.18 A Classic Display of Surface ECG and Intracardiac Recordings During an Electrophysiology Study of Supraventricular Tachycardia. *Left*, Included are four surface ECG leads, high right atrium (HRA) recording, two His bundle recordings (proximal and distal His [His_{prox} and His_{dist}]), five coronary sinus (CS) recordings (in a proximal-to-distal sequence), and a right ventricular apex (RVA) recording. The relative amplitudes of atrial and ventricular electrograms in CS recordings are also shown. *Right*, The back of the heart is shown with a CS catheter in position. The distal portion of the CS (CS_{dist}) is closer to the ventricle (originating as the great cardiac vein on the anterior wall); the CS crosses the atrioventricular groove at the lateral margin and becomes an entirely atrial structure as it empties into the right atrium. Thus, proximal CS (CS_{prox}) recordings show large atrial and small ventricular signals, whereas more distal recordings show small atrial, large ventricular signals. IVC, Inferior vena cava; PVs, pulmonary veins; SVC, superior vena cava.

His Bundle Electrogram

The HB catheter is positioned at the junction of the RA and RV. Therefore it records electrograms from local activation of the adjacent atrial, HB, and ventricular tissues (Fig. 4.19). Using a 5- to 10-mm bipolar recording, the His potential appears as a rapid biphasic spike, 15 to 25 milliseconds in duration, interposed between local atrial and ventricular electrograms. The use of a quadripolar catheter allows simultaneous recording of three bipolar pairs.

Before measuring conduction intervals within the HB electrogram, it is important to verify that the spike recorded between the atrial and ventricular electrograms on the HB catheter actually represents activation of the most proximal HB and not the distal HB or RB. The most proximal electrodes displaying the His potential should be chosen. Anatomically, the proximal portion of the HB originates in the atrial side of the tricuspid annulus; thus, the most proximal HB deflection is the one associated with the largest atrial electrogram. Recording a His potential associated with a small atrial electrogram can reflect a recording of the distal HB or RB and therefore would miss important intra-His conduction abnormalities and falsely shorten the measured His bundle–ventricular (HV) interval (see Fig. 4.19). Therefore even if a large His potential is recorded in association with a small atrial electrogram, the catheter should be withdrawn to obtain a His potential associated with a larger atrial electrogram. Using a multipolar electrode catheter to record simultaneously proximal and distal HB electrograms (e.g., a quadripolar catheter records three bipolar

electrograms over a 1.5-cm distance) can help evaluate intra-His conduction.

Validation of the HB recording can be accomplished by assessment of the HV interval and establishing the relationship between the His potential and other electrograms. The HV interval should be 35 milliseconds or longer (in the absence of preexcitation). In contrast, the RB potential invariably occurs within 30 milliseconds before ventricular activation. Atrial pacing can be necessary to distinguish a true His potential from a multicomponent atrial electrogram. With a true His potential, the AH interval should increase with incremental pacing rates. HB pacing can also be a valuable means for validating HB recording. The ability to pace the HB through the recording electrode and obtain HB capture (i.e., QRS identical to that during normal sinus rhythm [NSR] and stimulus-to-QRS interval identical to the HV interval during NSR) provides the strongest evidence validating the His potential. However, this technique is inconsistent in accomplishing HB capture, especially at low current output. Higher output can result in nonselective HB capture. The use of closely spaced electrodes and the reversal of current polarity (i.e., anodal stimulation) can facilitate HB capture. Failure to capture the HB selectively does not necessarily imply that the recorded potential is from the RB.

Other measures that can be used, although rarely required, to validate the HB recording include recording of pressure simultaneously with a luminal electrode catheter (which should reveal atrial pressure wave when the catheter is at the proximal His electrogram position) and simultaneous left and right recording of the His potential. The His

Fig. 4.19 Intracardiac Intervals. Shaded areas represent the P wave–atrial (PA) (blue), atrial–His bundle (AH) (pink), and His bundle–ventricular (HV) (yellow) intervals. It is important that the HV interval be measured from the onset of the His potential in the recording showing the most proximal (rather than the most prominent) His potential (His_{prox}) to the onset of the QRS on the surface ECG (rather than the ventricular electrogram on the His bundle recording). CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus; His_{dist} , distal His bundle; HRA , high right atrium; PRI , PR interval; RVA , right ventricular apex.

potential can be recorded in the noncoronary sinus of Valsalva (just above the aortic valve) or in the LVOT along the interventricular septum (just below the aortic valve). Because these sites are at the level of the central fibrous body, the proximal penetrating portion of the HB is recorded and can be used to time the His potential recorded via the standard venous route. Recording the HB from the noncoronary cusp (versus the LVOT) is preferred because only a true His potential can be recorded from that site.

Coronary Sinus Electrogram

Because the CS lies in the AV groove, in close contact to both the LA and the LV, the CS catheter records both atrial and ventricular electrograms. However, the CS has a variable relationship with the mitral annulus. The CS lies 2 cm superior to the annulus as it crosses from the RA to the LA. More distally, the CS frequently overrides the LV. Consequently, the most proximal CS electrodes (located at the CS os) are closer to the atrium and typically show a local sharp, large atrial electrogram and a smaller, far-field ventricular electrogram. The more distal CS electrodes, lying closer to the LV than the LA, record progressively smaller, less sharp, far-field atrial electrograms and larger, sharper, near-field ventricular electrograms (see Fig. 4.18).

During NSR, the atrial activation sequence proceeds from the proximal CS electrodes (positioned at the CS os) toward the distal CS electrodes. However, if the CS catheter is deeply seated in the CS, so that the most proximal electrodes are distal to the CS os and the most distal electrodes are anterolateral on the mitral annulus, then both proximal and distal electrodes can be activated at the same time (Fig. 4.20).

Right Ventricular Electrogram

The RV electrogram typically shows a local sharp and large ventricular electrogram and generally no atrial electrogram. The closer the RV catheter tip position is to the apex, the closer it is to the RB myocardial insertion site and the earlier the ventricular electrogram timing to the onset of the QRS. The catheter is usually positioned in the RV apex because of stability and reproducibility.

BASELINE INTERVALS

The accuracy of measurements made at a screen speed of 100 mm/s is ± 5 milliseconds, and at a speed of 400 mm/s is ± 1 millisecond. In dealing with large intervals (e.g., sinus node recovery time), a speed of 50 to 100 mm/s is adequate. For refractory periods, a speed of 150 to 200 mm/s is adequate, but for detailed mapping, a speed of 200 to 400 mm/s is required.

P Wave–Atrial Interval

The PA interval is measured from the first evidence of sinus node depolarization, whether on the intracardiac or surface ECG, to the atrial deflection recorded in the HB lead. It represents conduction through the RA to the inferoposterior atrial septum (i.e., the region of the AVN and HB; see Fig. 4.19).

The PA interval reflects conduction time from the sinus node to the AVN. A prolonged PA interval suggests abnormal atrial conduction and can be a clue to the presence of biatrial disease or disease confined to the RA. The normal range of the PA interval is 20 to 60 milliseconds. Rarely, diseased atrial conduction can underlie first-degree AV block,

Fig. 4.20 Influence of Catheter Position on Coronary Sinus (CS) Atrial Electrograms. Two different CS atrial activation sequences are shown from different patients. (A) A proximal-to-distal sequence is shown. (B) The latest activation is in the mid-CS electrodes. The diagrams at the bottom show relative positions of the CS catheter in each instance (atrioventricular grooves viewed from above). With more proximal CS position (CS_{prox}), propagation is proximal-distal, indicating relative distance from the sinus node. With a more distal CS position (CS_{dist}), the mid-CS electrodes are farthest from the sinus node. His_{dist} , Distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; HRA , high right atrium.

indicated by a prolonged PA interval. A short PA interval suggests an ectopic source of atrial activation.

Interatrial Conduction

Normal atrial activation begins in the high or mid-lateral RA (depending on the sinus rate), and spreads from there to the atrial septum, low RA and AV junction.

Activation of the LA is mediated by three possible routes. Superiorly, activation proceeds through the Bachman bundle; this can be seen in 50% to 70% of patients and can be demonstrated by CS os activation followed by distal CS and then mid-CS activation. Activation also propagates through the mid-atrial septum at the fossa ovalis and at the region of the central fibrous trigone at the apex of the triangle of Koch. The latter provides the most consistent amount of LA activation.

Interatrial conduction is measured by the interval between the atrial electrogram in the high RA lead and that in the CS lead. LA-to-RA activation during LA pacing appears primarily to cross the fossa and low septum and not the Bachman bundle, as reflected by relatively late high RA activation.

Normal retrograde atrial activation proceeds over the AVN. The earliest atrial activation is recorded in the AV junction (HB recording), then in the adjacent RA and CS os, and finally in the high RA and LA. More detailed mapping reveals atrial activation to start at the HB recording, with secondary breakthrough sites in the CS (reflecting activation over the LA extension of the AVN) or the posterior triangle of Koch. At faster ventricular pacing rates, the earliest atrial activation typically shifts to the posterior portion of the triangle of Koch, the CS os, or within the CS itself.

Atrial–His Bundle Interval

The AH interval is measured from the first rapid deflection of the atrial deflection in the HB recording to the first evidence of HB depolarization in the HB recording (see Fig. 4.19). The AH interval is an approximation of the AVN conduction time because it represents conduction time from the low RA at the interatrial septum through the AVN to the HB.

The AH interval can vary according to the site of atrial pacing. During LA or CS os pacing, the impulse can enter the AVN at a different site that bypasses part of the AVN, or it can just enter the AVN earlier in respect to the atrial deflection in the HB electrogram. Both mechanisms can give rise to a shorter AH interval.

The response of the AH interval to atrial pacing or drugs often provides more meaningful information about AVN function than an isolated measurement of the AH interval. Autonomic blockade with atropine (0.04 mg/kg) and propranolol (0.02 mg/kg) can be used to evaluate AVN function in the absence of autonomic influences. Not enough data, however, are available to define normal responses under these circumstances.

The AH interval has a wide range in normal subjects (50 to 120 milliseconds) and is markedly influenced by the autonomic nervous system. Short AH intervals can be observed in cases of increased sympathetic tone, reduced vagal tone, enhanced AVN conduction, and preferential LA input into the AVN, as well as unusual forms of preexcitation (atrio-His BTs).

Long AH intervals are usually caused by negative dromotropic drugs (such as digoxin, beta-blockers, calcium channel blockers, and antiarrhythmic drugs), enhanced vagal tone, and intrinsic disease of the AVN. Artificially prolonged AH intervals can result from an improperly positioned catheter or the incorrect identification of an RB potential as a His potential. This situation needs to be distinguished from true AH interval prolongation.

His Potential

His potential duration reflects conduction through the short length of the HB that penetrates the fibrous septum. Disturbances of HB conduction can manifest as fractionation, prolongation (longer than 30 milliseconds), or splitting of the His potential.

His Bundle–Ventricular Interval

The HV interval is measured from the onset of the His potential to the onset of the earliest registered surface or intracardiac ventricular activation. It represents conduction time from the proximal HB through the distal HPS to the ventricular myocardium (see Fig. 4.19).

The HV interval is not significantly affected by the autonomic tone, and it usually remains stable under normal conditions. The range of HV intervals in normal subjects is narrow, 35 to 55 milliseconds. A prolonged HV interval is consistent with diseased distal conduction in all fascicles or in the HB itself. A validated short HV interval suggests ventricular preexcitation via a BT. A falsely shortened HV interval can occur during sinus rhythm with PVCs or an accelerated idioventricular rhythm that is isorhythmic with the sinus rhythm, or when an RB potential rather than a His potential is inadvertently recorded.

PROGRAMMED ELECTRICAL STIMULATION

Stimulators

Cardiac stimulation is carried out by delivering a pulse of electrical current through the electrode catheter from an external pacemaker (stimulator) to the cardiac surface. Such an electrical impulse depolarizes cardiac tissue near the pacing electrode, which then propagates

through the heart. The paced impulses (stimuli) are introduced in predetermined patterns and at precise timed intervals using a programmable stimulator.

A typical stimulator has a constant current source and is capable of pacing at a wide range of cycle lengths (CLs), variable current strengths (0.1 to 10 mA), and pulse widths (0.1 to 10 milliseconds). In addition, current stimulators have at least two different channels of stimulation (preferably four) and allow delivery of multiple extrastimuli (three or more) and synchronization of the pacing stimuli to selected electrograms during intrinsic or paced rhythms.

Pacing Techniques

Pacing Output

Stimulation is usually carried out using an isolated constant current source that delivers a rectangular impulse. Pacing output at twice (2×) diastolic threshold is generally used. *Pacing threshold* is defined as the lowest current required for consistent capture determined in late diastole with a stimulus of a given duration. The pacing threshold can be influenced by the pacing cycle length (PCL); therefore the threshold should be determined at each PCL used. In general, refractory periods are somewhat longer when determined using 2× threshold (as opposed to higher outputs), and this can reduce the incidence of induction of nonclinical tachyarrhythmias. In addition, diastolic excitability can be influenced by drug administration; reevaluation of the pacing threshold and adjustment of the pacing output (2× threshold) are therefore required in such situations. A pulse duration of 1 or 2 milliseconds is generally used.

High current strength is generally used for determination of strength-interval curves to overcome drug-induced prolongation of refractoriness, assess the presence and mechanism of antiarrhythmic therapy, and overcome the effect of decreased tissue excitability (e.g., pace mapping in scar-related arrhythmias).

Cycle Length

During EP testing, CLs often change from beat to beat, so that these measures are more relevant than an overall rate expressed in beats per minute. The use of rates in beats per minute is retained mostly to facilitate communication with physicians who are more comfortable with this terminology. Pacing rate (per min) is determined by dividing 60,000 (milliseconds/min) by the CL (in milliseconds).

Incremental Versus Decremental

The terms *incremental* and *decremental* can have opposite meaning, depending on whether one is considering the pacing rate in beats per minute or the PCL in milliseconds. The term *incremental pacing rate* is derived from stimulators controlled by an analog dial. Digitally controlled devices often increase the rate by choosing a sequence of CL decrements, but the term *incremental pacing* may still be used.

Overdrive Pacing (“Straight Pacing”)

Pacing stimuli are delivered at a constant pacing rate (constant PCL) throughout the duration of the stimulation. The pacing rate is faster than the rate of the baseline rhythm to ensure capture of the spontaneous rhythm.

Burst Pacing

Pacing stimuli are delivered at a constant rate for a relatively short duration, but at successively faster rates with each burst until a predetermined maximum rate (or minimum PCL) has been reached. This technique is generally used for induction or termination of tachycardias.

Stepwise Rate-Incremental Pacing

After pacing at a given rate for a predetermined number of stimuli or seconds, the rate is increased (with intervening pauses) in a series of steps until predetermined endpoints are reached. It is important to maintain the pacing at any given rate for at least 15 seconds (period of accommodation) before increasing the pacing rate. Otherwise, the initial stimuli at any given rate can produce effects different from those observed several seconds later because the ability of a tissue to conduct is affected by the baseline rate or CL of the preceding beats. A disadvantage for this technique is the prolonged pacing required at each rate, which is time-consuming.

Ramp Pacing

Ramp pacing implies a smooth change in the interval between successive stimuli, with gradual decrease of the PCL every several paced complexes (without intervening pauses). Ramps are often used as an alternative to the stepwise method for assessment of conduction. The pacing rate is slowly increased at 2 to 4 beats/min every several paced beats until block occurs. This method is particularly useful when multiple assessments of conduction are planned (e.g., after therapeutic interventions) and in the assessment of retrograde conduction. Because each successive paced interval differs from its predecessor by only a few milliseconds, the interval at which block occurs can be determined more precisely using the ramp method. However, prolonged episodes of continuous high-rate pacing can provoke significant hypotension, and close monitoring of blood pressure is important while performing these maneuvers.

For tachycardia induction or termination, the ramp is decreased in duration, but the inter-stimulus intervals are decreased more rapidly. Ramp pacing is generally used in antitachycardia pacing algorithms in ICDs. Programmed rate-incremental ramps are also known as *auto-decremental pacing*.

Extrastimulus Technique

S_1 - S_1 drive stimuli. The heart is paced, or driven, at a specified rate and duration (typically eight paced beats) after which a premature extrastimulus is delivered. The eight drive beats are each termed S_1 stimulus. The S_1 - S_1 drive stimuli are sometimes called trains. These S_1 drive stimuli can be followed by first, second, third, and n th premature extrastimuli, which are designated as S_2 , S_3 , S_4 , and S_N . When the extrastimuli follow a series of sinus beats, the sinus beats can also be designated as S_1 .

S_1 , S_2 , S_3 , ..., S_N . S_2 is the first extrastimulus, with the S_1 - S_2 interval almost always shorter than the S_1 - S_1 interval. S_3 , S_4 , ..., S_N are the second, third, ..., n th extrastimuli. When stimulation is performed in the atrium, capture of S_1 , S_2 , S_3 , ..., S_N results in atrial depolarizations, termed A_1 , A_2 , A_3 , ..., A_N , respectively, and when stimulation is performed in the ventricle, they are termed V_1 , V_2 , V_3 , ..., V_N , corresponding to the resultant ventricular depolarizations, respectively.

One or more extrastimuli (designated S_2 , S_3 , and S_N) are introduced at specific coupling intervals based on previous S_1 drive stimuli or spontaneous beats. Thereafter, the S_1 - S_2 interval is altered, usually in 10- to 20-millisecond steps, until an endpoint is reached, such as tissue refractoriness or termination or induction of a tachycardia. It is usual to begin late in diastole and successively decrement the S_1 - S_2 interval. A second extrastimulus (S_3) can then be introduced, with the S_2 - S_3 interval altered similarly to that used for S_1 - S_2 .

Two methods are in common clinical use for decreasing the coupling intervals during delivery of multiple extrastimuli. In the simple sequential method, the S_1 - S_2 coupling interval is decreased until it fails to capture, at which time the coupling interval is increased until it captures (usually within 10 to 20 milliseconds). The S_1 - S_2 coupling interval is then held

constant while the S_2 - S_3 interval is decreased similarly to that used for S_1 - S_2 , and then the same is done for S_3 - S_4 . In the tandem method, the S_1 - S_2 coupling interval is decreased until S_2 fails to capture, and then the S_1 - S_2 coupling interval is increased by 40 to 50 milliseconds and held there. S_3 is then introduced and the S_2 - S_3 interval decreased until S_3 fails to capture. At that point, the S_1 - S_2 interval is decreased, and S_3 is retested to see whether it captures. From that point on, the S_1 - S_2 and S_2 - S_3 intervals are decreased in tandem until refractory. As compared with the simple sequential method, the tandem method allows relatively longer intervals and provides a larger number of stimulation runs before moving on to the next extrastimulus. Prospective studies comparing the two methods have shown no differences between the two methods in any of the outcomes assessed.⁵⁹

Ultrarapid Train Stimulation

Pacing at very short CLs (10 to 50 milliseconds) is rarely performed, mainly for induction of ventricular fibrillation (VF), to test defibrillation threshold during implantation of a cardioverter-defibrillator.

Conduction and Refractoriness

Conduction

During depolarization, the electrical impulse spreads along each cardiac cell, and rapidly from cell to cell, because each myocyte is connected to its neighbors through low resistance gap junctions. As discussed in **Chapter 1**, conduction velocity refers to the speed of propagation of an electrical impulse through cardiac tissue, which is dependent on both the active membrane properties of the individual cardiac myocyte that generates the action potential (i.e., electrical excitability and refractoriness) and passive properties governing the flow of current between cardiac cells (cell-to-cell coupling and tissue geometry).⁶⁰

Conduction can be assessed by observing the propagation of wavefronts during pacing at progressively incremental rates. Rate-incremental pacing is delivered to a selected site in the heart while propagation to a selected distal point is assessed. Conduction velocity is assessed by measuring the time it takes for an impulse to travel from one intracardiac location to another. During tests of conduction, it is usual for capture to be maintained at the site of stimulation and block to occur at a distal point.

Refractoriness

As discussed in **Chapter 1**, during a cardiac cycle, once an action potential is initiated, the cardiac cell is inexcitable to stimulation (i.e., unable to initiate another action potential in response to a stimulus of threshold intensity) for some duration of time (which is slightly shorter than the "true" action potential duration) until its membrane has repolarized to a certain level.⁶⁰⁻⁶²

There are different levels of refractoriness during the action potential. During the *absolute refractory period* (which extends over phases 0, 1, 2, and part of phase 3 of the action potential), the tissue is completely inexcitable and a second action potential absolutely cannot be initiated, no matter how large a stimulus is applied, because of the inactivation of the majority of Na^+ channels. After the absolute refractory period, a stimulus may cause some cellular depolarization but does not lead to a propagated action potential. The sum of this period (which includes a short interval of phase 3 of the action potential) and the absolute refractory period is termed the *effective refractory period* (ERP).

The ERP is followed by the *relative refractory period* (RRP), which extends over the middle and late parts of phase 3 of the action potential. During the RRP, initiation of a second action potential is *repressed* but not impossible; a larger-than-normal stimulus can result in activation of the cell and lead to a propagating action potential. However, the

upstroke of the new action potential is less steep and of lower amplitude and its conduction velocity slower than normal. Of note, there is a brief period in phase 3 of the action potential, the *supernormal period*, during which excitation is possible in response to an otherwise subthreshold stimulus; that same stimulus fails to elicit a response earlier or later than the supernormal period (see later).

Measurements of Refractory Periods

Refractoriness or, more appropriately, *excitability* is defined by the response of a tissue to premature stimulation. Refractory periods are analyzed by the extrastimulus technique, with progressively premature extrastimuli delivered after a train of 8 to 10 paced beats at a fixed PCL to allow for reasonable (more than 95%) stabilization of refractoriness, which is usually accomplished after 3 or 4 paced beats.

Several variables are considered in the assessment of refractory periods, including the stimulus amplitude and the basic drive CL. Longer drive CLs are generally associated with longer refractory periods. However, refractory periods of different parts of the conducting system do not respond comparably with changes in the drive CLs.⁶³

In addition, the measured ERP is invariably related to the current used. Thus, standardization of the pacing output is required. In most laboratories, it is arbitrarily standardized at twice the diastolic threshold. A more detailed method of assessing refractoriness is to define the strength-interval curves at these sites. The steep portion of that curve defines the ERP of that tissue. The use of increasing current strengths to 10 mA usually shortens the measured ERP by approximately 30 milliseconds. However, such a method does not offer a useful clinical advantage, except when the effects of antiarrhythmic drugs on ventricular excitability and refractoriness are to be characterized. Moreover, the safety of using high current strengths, especially when multiple extrastimuli are delivered, is questionable because fibrillation is more likely to occur in such situations.

It is important that measurements of refractory periods be taken at specific sites. Measurements of atrial and ventricular ERP are taken at the site of stimulation. Measurements of AVN ERP and HPS ERP are taken from responses in the HB electrogram.

Effective refractory period. The ERP is the longest premature coupling interval (S_1 - S_2) at a designated stimulus amplitude (usually $2\times$ diastolic threshold) that results in failure of propagation of the premature impulse through a tissue (i.e., fails to capture). ERP therefore must be measured proximal to the refractory tissue.

Relative refractory period. The RRP is defined as the longest premature coupling interval (S_1 - S_2) that results in prolonged conduction of the premature impulse (an increase in stimulus to distal response time) compared with the conduction of the stimulus delivered during the basic drive train. Conduction is slowed when a wavefront

encounters tissue that is not completely repolarized. Thus, the RRP marks the end of the full recovery period (i.e., the zone during which conduction of the premature and basic drive impulses is identical). The RRP is generally slightly longer than the ERP by an amount called the *latency period*. During the latency period, the tissue is excitable, but the excitation wavefront conducts with slower or even decremental conduction.

Functional refractory period. The functional refractory period (FRP) is the shortest interval between two consecutively conducted impulses out of a cardiac tissue resulting from any two consecutive input impulses into that tissue (i.e., the shortest output interval that can occur in response to *any* input interval in a particular tissue). Because the FRP is a measure of output from a tissue, it is described by measuring points distal to that tissue. It is helpful to think of the FRP as a response-to-response measurement (in contrast, the ERP is a stimulus-to-stimulus measurement). Therefore the FRP is a measure of both refractoriness *and* conduction velocity of a tissue. The definitions of anterograde ERP and FRP of the AV conduction system are given in Table 4.1.

Cycle Lengths Responsiveness of Refractory Periods

Normally, refractoriness of the atrial, HPS, and ventricular tissue is directly related to the basic drive CL (i.e., the ERP shortens with decreasing drive CL). This phenomenon results from rate-related shortening of the action potential duration and is most marked in the HPS. Abrupt changes in the CL also affect refractoriness of these tissues. A change from a long to short CL (e.g., with introduction of an extrastimulus [S_2] following a pacing drive [S_1] with a long CL) shortens the ERP of the HPS and atrium, whereas a change from a short to a long drive CL markedly prolongs the HPS ERP but alters the ventricular ERP little, if at all. Refractoriness of the atrial, HPS, and ventricular tissue appears relatively independent of autonomic tone; however, data have shown that increased vagal tone can potentially shorten atrial ERP and prolong ventricular ERP.⁶³ CL shorting can affect different structures differently. For example, normally at relatively long cycle lengths, the RB ERP exceeds that of the left bundle (LB), so that functional right bundle branch block (RBBB) is common. At short CLs, the LB ERP exceeds that of the RB so that left bundle branch block (LBBB) is more common.

In contrast, the AVN ERP increases with increasing drive CL in response to the fatigue phenomenon, which most likely results because AVN refractoriness is time-dependent and exceeds its action potential duration (unlike HPS refractoriness). In addition, AVN refractory periods are labile and can be markedly affected by the autonomic tone. On the other hand, the response of AVN FRP to changes in PCL is variable, but it tends to decrease with decreasing PCL. This paradox occurs because the FRP is not a true measure of refractoriness encountered by an atrial

TABLE 4.1 Definition of Refractory Periods

	ERP	RRP	FRP
Atrium	Longest S_1 - S_2 interval that fails to achieve atrial capture	Longest S_1 - S_2 interval at which S_2 - A_2 is $>S_1$ - A_1	Shortest A_1 - A_2 interval (recorded at a designated site, often the HB region) in response to any S_1 - S_2
AVN	Longest A_1 - A_2 interval (measured at the HB region) that fails to propagate to the HB	Longest A_1 - A_2 interval at which A_2 - H_2 is $>A_1$ - H_1	Shortest H_1 - H_2 interval in response to any A_1 - A_2
HPS	Longest H_1 - H_2 interval that fails to propagate to the ventricles	Longest H_1 - H_2 interval at which H_2 - V_2 is $>H_1$ - V_1 or generates an aberrant QRS complex	Shortest V_1 - V_2 interval in response to any H_1 - H_2
Ventricle	Longest S_1 - S_2 interval that fails to achieve ventricular capture	Longest S_1 - S_2 interval at which S_2 - V_2 is $>S_1$ - V_1	Shortest V_1 - V_2 interval (recorded at a designated site or) in response to any S_1 - S_2

extrastimulus (atrial extrastimulus [AES]; A₂); it is significantly determined by the AVN conduction time of the basic drive beat (A₁-H₁); the longer the A₁-H₁ is, the shorter the calculated FRP will be at any A₂-H₂.

Limitations of Tests of Conduction and Refractoriness

It is unusual to be able to collect a complete set of measurements. With refractory period testing, the atrial ERP is often longer than the AVN ERP, so that atrial refractoriness is encountered before AVN refractoriness, thus limiting the ability to assess the latter. Moreover, an AES cannot be used to test the HPS if conduction is blocked at the AVN level. This is a limitation that applies to most patients undergoing conduction or refractory period testing. On the other hand, it is possible to assess anterograde conduction and refractoriness distal to the AVN by direct pacing of the HB. This is not part of the routine EP evaluation, however, and is reserved for cases in which the information is particularly desired.

It is important to note that atrial conduction can materially affect the determination of refractory periods. Therefore refractory periods should not be timed from the site of stimulation, but from the point in the conduction cascade that is being assessed. For example, if the high RA is stimulated in a patient with a left lateral BT, an early AES can encounter the RRP of the atrium, so that intraatrial conduction time is prolonged. Thus, the timing of the S₁-S₂ stimuli in the high RA would be shorter than the timing of the propagated impulse when it arrives at the region of the BT as the local A₁-A₂ interval.

A wide range of normal values has been reported for refractory periods (Table 4.2). However, it is difficult to interpret these so-called normal values because they come from pooled data using different standards (different PCLs, stimulus strengths, and pulse widths).

ATRIAL STIMULATION

Technical Aspects

Atrial stimulation provides a method for evaluation of the functional properties of the sinus node and AV conduction system and of the means of induction of different arrhythmias (supraventricular and, occasionally, ventricular arrhythmias). Atrial stimulation from different atrial sites can result in different patterns of AV conduction. Thus, stimulation should be performed from the same site if the effects of drugs and physiological maneuvers are to be studied. Atrial stimulation is usually performed from the high RA and CS.

Rate-incremental atrial pacing is usually started at a PCL just shorter than the sinus CL, with progressive shortening of the PCL (by 10- to 20-millisecond decrements) until 1:1 atrial capture is lost, Wenckebach AVN block develops, or a PCL of 200 to 250 milliseconds is reached. Ramp atrial pacing is equivalent to rate-incremental pacing if AVN Wenckebach CL is all that is required. Stepwise rate-incremental pacing,

however, also allows evaluation of sinus node recovery time at each drive CL. Atrial pacing should always be synchronized because alteration of the coupling interval of the first paced beat of the pacing drive can affect subsequent AV conduction.

During stepwise rate-incremental pacing, pacing should be continued long enough (usually 15 to 60 seconds) at each PCL to ensure stability of conduction intervals and to overcome two factors that significantly influence the development of a steady state: the phenomenon of accommodation and the effects of autonomic tone. During rate-incremental pacing, if the coupling interval of the first beat of the drive is not synchronized, it can be shorter, longer, or equal to the subsequent PCL. Therefore one can observe an increasing, decreasing, or stable AH interval pattern for several cycles, and the initial AH interval can be different from the steady-state AH interval. Oscillations of the AH interval, which dampen to a steady level, or the AVN Wenckebach can occur under these circumstances. Regarding the influence of the autonomic tone on AVN conduction, rapid pacing can produce variations in AVN conduction, depending on the patient's immediate autonomic state. Rapid pacing can also provoke symptoms or hypotension in patients who then produce neurohumoral responses that can alter results. Therefore for assessment of AV conduction, ramp pacing is often an attractive alternative to the stepwise method. The pacing rate is slowly increased at 2 to 4 beats/min per second (or the PCL is decreased by 10 milliseconds every several paced beats) until block occurs.

AES is used to assess of atrial and AVN refractory periods and to induce arrhythmias. During programmed stimulation, a sequence of eight paced stimuli is delivered at a constant rate (the S₁ drive), which allows stable AVN conduction. Following these eight beats, an AES (S₂) is delivered. This stimulation sequence is repeated at progressively shorter S₁-S₂ coupling intervals, thus allowing the response of the sinus node and AVN to be recorded across a range of premature test stimuli.

Normal Response to Rate-Incremental Atrial Pacing Sinus Node Response to Atrial Pacing

The sinus node is the prototype of an automatic focus. Automatic rhythms are characterized by spontaneous depolarization, overdrive suppression, and post-overdrive warm-up to baseline CL. Rapid atrial pacing results in overdrive suppression of the sinus rate, with prolongation of the return sinus CL following termination of the pacing train. Longer pacing trains and faster pacing rates further prolong the return cycle. After cessation of pacing, the sinus rate resumes discharge at a slower rate and gradually speeds up (warms up) to return to the pre-pacing sinus rate.

Sinus node recovery time is the interval between the end of a period of pacing-induced overdrive suppression of sinus node activity and the return of sinus node function, manifested on the surface ECG by a post-pacing sinus P wave.

Fig. 4.21 Normal Atrioventricular Node (AVN) Response to Rate-Incremental Atrial Pacing. (A) Fixed-rate high right atrial (HRA) pacing (S) at a cycle length (CL) of 600 milliseconds. (B) Decreasing the pacing CL to 500 milliseconds results in prolongation of the atrial–His bundle (AH) interval, as illustrated in the His bundle recording (His). Infranodal conduction (His bundle–ventricular interval) remains unaffected. (C) Further decrement of the pacing CL results in progressive prolongation of the AH interval until block occurs in the AVN (AVB), followed by resumption of conduction, indicating Wenckebach CL. The site of block is in the AVN because no His bundle deflection is present after the nonconducted atrial stimulus. Of note, apparent block of another atrial stimulus is observed (pseudoblock) because of failure of the atrial stimulus to capture (NC), which is confirmed by the absence of an atrial electrogram on the His bundle recording after the stimulus artifact.

Atrioventricular Node Response to Atrial Pacing

The normal AVN response to rate-incremental atrial pacing is for the PR and AH intervals to increase gradually as the PCL decreases until AVN Wenckebach block appears (Fig. 4.21). With further decrease in the PCL, higher degrees of AV block (2:1 or 3:1) can appear. Infranodal conduction (HV interval) generally remains unaffected.

Wenckebach block is frequently atypical; that is, the AH interval does not increase gradually in decreasing increments but stabilizes for several beats before the block, or it can show its greatest increment in the last conducted beat. The incidence of atypical Wenckebach periodicity from Mobitz II AV block. In addition, it is important to ensure that the ventricular pauses observed during atrial pacing are not secondary to loss of atrial capture or the occurrence of AVN echo beats (pseudoblock; see Fig. 4.21).

AVN Wenckebach CL is the longest PCL at which Wenckebach block in the AVN is observed. Normally, Wenckebach CL is 500 to 350 milliseconds, but it is sensitive to the autonomic tone. There is a correlation between the AH interval during NSR and the Wenckebach CL; patients

with a long AH interval during NSR tend to develop Wenckebach block at a longer PCL, and vice versa.

At short PCLs (less than 350 milliseconds), infranodal block can occasionally occur in patients with normal baseline HV interval and QRS complex. This occurs especially when atrial pacing is started during NSR with the first or second paced impulses acting as a long-short sequence. The HPS can also show accommodation following the initiation of pacing. Prolongation of the HV interval or infranodal block at a PCL longer than 400 milliseconds is abnormal and indicates infranodal conduction abnormalities.

Atrial Response to Atrial Pacing

It is usually possible to maintain 1:1 atrial capture with rate-incremental pacing techniques to a PCL of 200 to 300 milliseconds. Pacing threshold normally tends to increase at faster rates. Rate-incremental pacing can result in prolongation of the intraatrial (PA interval) and interatrial conduction. At rapid pacing rates, induction of AF is not rare and is not necessarily an abnormal response. Vagal tone and medications such as adenosine and edrophonium can slow the sinus rate, but they tend

to shorten the atrial ERP, which makes the atrium more vulnerable to induction of AF.

Normal Response to Atrial Premature Stimulation

Sinus Node Response to Atrial Extrastimulation

Four zones of response of the sinus node to AES have been identified: the zone of collision, the zone of reset, the zone of interpolation, and the zone of reentry (Fig. 4.22).

Zone I. A late-coupled AES with very long A_1 - A_2 intervals (with A_2 falling in the last 20% to 30% of the sinus CL) collides with the impulse already emerging from the sinus node, resulting in fusion of atrial activation (fusion between the AES [A_2] with the spontaneous sinus impulse [A_1]) or paced-only atrial activation sequence; it fails to affect the timing of the next sinus beat, thus producing a fully compensatory pause. This zone, also known as the zone of collision, zone of interference, and nonreset zone, is defined by the range of A_1 - A_2 at which A_2 - A_3 is fully compensatory (see Fig. 4.22).

Zone II. An earlier coupled AES results in penetration of the sinus node with resetting so that the resulting pause is less than compensatory (i.e., A_1 - A_3 is $< 2 \times [A_1$ - $A_1]$), but without changing sinus node automaticity. The range of A_1 - A_2 at which resetting of the sinus pacemaker occurs, resulting in a less than compensatory pause, defines zone II, also known as the zone of reset (see Fig. 4.22). This zone is typically of long duration (40% to 50% of the sinus CL). In most patients, A_2 - A_3 remains constant throughout zone II, thus producing a plateau in the curve because, although A_2 penetrates and resets the sinus node, it does so without changing the sinus pacemaker automaticity. Hence, A_2 - A_3 should equal the spontaneous sinus CL (A_1 - A_1) plus the time it takes the AES (A_2) to enter and exit the sinus node. The difference between A_2 - A_3 and A_1 - A_1 therefore has been taken as an estimate of total sinoatrial conduction time.

Zone III. A very early coupled AES encounters a refractory sinus node (following the last sinus discharge) and fails to enter or reset the sinus node. The next sinus discharge is on time because the atrium is already fully recovered following that early AES. The range of A_1 - A_2 coupling intervals at which A_2 - A_3 is less than A_1 - A_1 , and A_1 - A_3 is less than $2 \times (A_1$ - A_1), defines zone III, also known as the zone of interpolation (see Fig. 4.22). The A_1 - A_2 coupling intervals at which incomplete interpolation is first observed define the RRP of the perinodal tissue. Some refer to this as the sinus node refractory period. In this case, A_3 represents delay of A_1 exiting the sinus node, which has not been affected. The A_1 - A_2 coupling interval at which complete interpolation is observed probably defines the ERP of the most peripheral of the perinodal tissue because the sinus impulse does not encounter refractory tissue on its exit from the sinus node. In this case, $(A_1$ - A_2) + $(A_2$ - A_3) = A_1 - A_1 and sinus node entrance block is said to exist.

Zone IV. This zone, also known as the zone of reentry, is defined as the range of A_1 - A_2 at which A_2 - A_3 is less than A_1 - A_1 , $(A_1$ - A_2) + $(A_2$ - A_3) is less than A_1 - A_1 , and the atrial activation sequence and P wave morphology are identical to those of the sinus. The incidence of single beats of sinus node reentry is approximately 11% in the normal population.

Atrioventricular Nodal Response to Atrial Extrastimulation

Progressively premature AES results in prolongation of PR and AH intervals, with inverse relationship between the AES coupling interval (A_1 - A_2) and the AH interval (A_2 - H_2). The shorter the coupling interval of the AES is, the longer the A_2 - H_2 interval will be (see Fig. 4.22). More premature AES can block in the AVN with no conduction to the ventricle (defining AVN ERP). Occasionally, conduction delay and block occur in the HPS, especially when the AES is delivered following long basic drive CLs, because HPS refractoriness frequently exceeds the AVN FRP at long PCLs.

Fig. 4.22 Normal Sinus Node and Atrioventricular Node Response to Atrial Extrastimulation. (A) Baseline sinus rhythm shown in surface ECG lead II, high right atrium (HRA) recording, and His bundle (His) recording. The shaded area represents two sinus cycle lengths ($2 \times [A_1$ - $A_1]$). (B) A late coupled atrial extrastimulus (AES; A_2) collides with the exiting sinus impulse and therefore does not affect (or reset) the sinus pacemaker (zone of collision). The next sinus impulse (A_3) occurs at exactly twice the baseline sinus cycle length. (C) An early coupled AES is able to penetrate and reset the sinus node (zone of resetting). (D) An even earlier coupled AES reaches refractory tissue around the sinus node and is thus unable to penetrate the sinus node (entrance block); therefore it does not affect sinus node discharge. The next spontaneous sinus beat (A_3) arrives exactly at the sinus interval (zone of interpolation). The atrial-His bundle interval progressively prolongs with progressively premature coupling intervals (B to D). In contrast, the His bundle-ventricular (HV) interval remains constant.

The patterns of AV conduction can be expressed by plotting refractory period relating the A_1 - A_2 interval to the responses of the AVN and HPS. Plotting the A_1 - A_2 interval versus the H_1 - H_2 and V_1 - V_2 intervals illustrates the functional input-output relationship between the basic drive beat and the AES and provides an assessment of the FRP of the AV conduction system. In contrast, plotting the A_2 - H_2 interval (AVN conduction time of the AES) and the H_2 - V_2 interval (HPS conduction time of the AES) versus the A_1 - A_2 interval (the AES coupling interval) allows determination of the conduction times through the various components of the AV conduction system.

Type I response. In this type, the progressively premature AES encounters progressive delay in the AVN without any changes in the HPS. Therefore refractoriness of the AVN determines the FRP of the entire AV conduction, and the ERP of the AV conduction system is determined at the atrial or AVN level. This response is characterized by initial shortening of the H_1 - H_2 and V_1 - V_2 intervals as the AES coupling interval (A_1 - A_2) shortens, whereas AVN conduction (A_2 - H_2) and HPS conduction (H_2 - V_2) remain stable (eFig. 4.7). With further shortening of the A_1 - A_2 interval, the RRP of the AVN is encountered, resulting in progressive delay in AVN conduction (manifesting as progressive prolongation of the A_2 - H_2 interval) accompanied by stable HPS conduction (H_2 - V_2) and a progressive but identical prolongation of both the H_1 - H_2 and V_1 - V_2 intervals, until the AES is blocked within the AVN (AVN ERP) or until the atrial ERP is reached. The minimum H_1 - H_2 and V_1 - V_2 intervals attained define the FRP of the AVN and entire AV conduction system. AVN conduction (A_2 - H_2) usually increases by 2 to 3× baseline values before block.

Type II response. In type II response, conduction delay occurs initially in the AVN; however, with further shortening of the AES coupling interval, progressive delay develops in the HPS. Therefore refractoriness of the HPS determines the FRP of the entire AV conduction system, and the ERP of the AV conduction system is determined at any level. At longer A_1 - A_2 intervals, type II response is similar to type I response; however, as the A_1 - A_2 interval shortens, conduction delay develops initially in the AVN (manifesting as progressive prolongation of the A_2 - H_2 interval) but then in the HPS (manifesting as aberrant QRS conduction and progressive prolongation of the H_2 - V_2 interval) as the RRP of the HPS is encountered. Therefore in contrast to type I response, both A_2 - H_2 and H_2 - V_2 intervals prolong in response to progressively shorter A_1 - A_2 , resulting in divergence in the H_1 - H_2 and V_1 - V_2 curves until the AES is blocked within the AVN (AVN ERP), in the HPS (HPS ERP), or until the atrial ERP is reached (see eFig. 4.7). Block usually occurs in the AVN, but it can occur in the atrium and occasionally in the HPS (modified type II response). AVN conduction (A_2 - H_2) usually increases only modestly (by less than 2× baseline values before block).

Type III response. In type III response, conduction delay occurs initially in the AVN; however, at a critical AES coupling interval, sudden and marked delay develops in the HPS. Therefore refractoriness of the HPS determines the FRP of the entire AV conduction system, and the ERP of the AV conduction system is determined at any level. However, in contrast to type II response, the HPS is invariably the first site of block. At longer A_1 - A_2 intervals, type II response is similar to type I response; however, as the A_1 - A_2 interval shortens, progressive delay is noted initially in the AVN (manifest as progressive prolongation in the A_2 - H_2 interval), but then a sudden delay of conduction in the HPS occurs (manifesting as aberrant QRS conduction and a sudden jump in the H_2 - V_2 interval). This results in a break in the V_1 - V_2 curve, which subsequently descends until, at a critical A_1 - A_2 interval, the impulse blocks in the AVN or HPS (see eFig. 4.7). The FRP of the HPS occurs just before the marked jump in H_2 - V_2 . AVN conduction (A_2 - H_2) usually increases by less than 2× baseline values before block.

Type I response is the most common pattern, whereas type III response is the least common. The pattern of AV conduction (type I, II, or III), however, is not fixed in any patient. Drugs (e.g., atropine, isoproterenol) or changes in CL can alter the refractory period relationship among different tissues so that one type of response can be switched to another. For example, atropine can decrease the FRP of the AVN and allow the impulse to reach the HPS during its RRP, changing type I response to type II or III.

Not infrequently, the ERP of the atrium is reached earlier than that of the AVN, especially when the basic drive is slow (which increases atrial ERP and decreases AVN ERP) or when the patient is agitated, which increases sympathetic tone and decreases AVN ERP. The first site of block is in the AVN in most patients (45%), in the atrium in 40%, and in the HPS in 15%.

Atrial Response to Atrial Extrastimulation

Early AESs can impinge on the atrial RRP, with resulting local latency (i.e., long interval between the pacing artifact and the atrial electrogram on the pacing electrode). A very early AES delivered during the atrial ERP fails to capture the atrium. The atrial ERP can be longer or shorter than the AVN ERP, especially at long basic drive CLs or in cases of enhanced AVN conduction secondary to autonomic influences.

As with rate-incremental pacing, AES can result in prolongation of intraatrial and interatrial conduction, which is more pronounced in patients with a history of atrial arrhythmias. Development of a fractionated atrial electrogram is more often observed in patients who have a history of AF. Intraatrial block in response to AES is unusual. Occasionally, double or triple AESs induce AF in patients with no history of such arrhythmia. Such episodes usually terminate spontaneously and are not clinically relevant in the absence of a history of known or suspected atrial arrhythmias.

Repetitive Atrial Responses

Atrial stimulation can trigger extraatrial complexes or echo beats. Those complexes can be caused by different mechanisms; the most common are intraatrial reentrant beats and AVN echo beats.

Intraatrial reentrant beats usually occur at short coupling intervals. They can originate anywhere in the atrium, and atrial activation sequence depends on the site of origin of the beat. The incidence of these responses increases with increasing the number of AESs, the number of drive PCLs, and the number of stimulation sites used.

Repetitive atrial responses can also be caused by reentry in the AVN. These patients have anterograde dual AVN physiology, and the last paced beat conducts slowly down the slow AVN pathway and then retrogradely up the fast pathway to produce the echo beat (Fig. 4.23). Atrial activation sequence is consistent with retrograde conduction over the fast AVN pathway, earliest in the HB catheter recording. Atrial and ventricular activations occur simultaneously.

VENTRICULAR STIMULATION

Technical Aspects

Ventricular stimulation is used to assess retrograde ventricular-atrial (VA) conduction and refractory periods, retrograde atrial activation patterns, including sequences that can indicate the presence of a BT, and vulnerability to inducible ventricular arrhythmias.

Stepwise rate-incremental ventricular pacing or ramp pacing is used in the assessment of VA conduction. It is unusual to provoke ventricular arrhythmias with these tests, even in patients with known ventricular arrhythmia. Rate-incremental ventricular pacing is usually started at a PCL just shorter than the sinus CL, and the PCL is then gradually decreased (in 10- to 20-millisecond decrements) down to 300

eFig. 4.7 Patterns of Atrioventricular Conduction Response to Atrial Extrastimulation (AES). (A and B) Type I pattern of atrioventricular node response to AES. Fig. 4.23 Anterograde Dual Atrioventricular Nodal Pathways. *Top*, A single extrastimulus is introduced from the high right atrium (HRA; S_2) at 290 milliseconds after the last drive stimulus (S_1). This results in an atrial-His bundle (AH) interval of 140 milliseconds. *Bottom*, An extrastimulus is delivered 10 milliseconds earlier than above (280 milliseconds), resulting in marked prolongation of the AH interval to 202 milliseconds and an atrial echo. milliseconds. Shorter PCL may be used to assess rapid conduction in patients with supraventricular tachycardia (SVT) or to induce VT. With ramp pacing, the pacing rate is slowly increased at 2 to 4 beats/min per second (or the PCL is decreased by 10 milliseconds every several paced beats) until VA block occurs.

Ventricular extrastimulus (VES) testing is used to assess ventricular, HPS, and AVN refractory periods and to induce arrhythmias. During programmed stimulation, a sequence of eight paced stimuli is delivered at a constant rate (the S_1 drive), which allows stable VA conduction. Following these eight beats, a VES (S_2) is delivered. This stimulation sequence is repeated at progressively shorter S_1 - S_2 intervals, thus allowing the response of the HPS and AVN to be recorded across a range of premature test stimuli.

During ventricular stimulation, the HB electrogram shows a retrograde His potential in 85% of patients with a normal QRS during NSR. Ventricular pacing at the base of the heart close to the AV junction

facilitates recording a retrograde His potential because it allows the ventricles to be activated much earlier relative to the HB (Fig. 4.24). The VH or stimulus-HB (S-H) interval always exceeds the anterograde HV interval by the time it takes for the impulse to travel from the stimulation site to the ipsilateral bundle branch. In patients with normal HV intervals, a retrograde His potential can usually be seen before the ventricular electrogram in the HB recording during RV apical pacing. In contrast, when ipsilateral bundle branch block (BBB) is present, especially with long HV intervals, a retrograde His potential is less frequently seen; when it is seen, it is usually inscribed after the QRS when pacing from the ipsilateral ventricle (eFig. 4.8).

Ventricular stimulation is relatively safe; however, induction of clinically irrelevant serious arrhythmias, including VF, can occur in patients with normal hearts and those who have not had spontaneous ventricular arrhythmias. The induction of these arrhythmias is directly related to the aggressiveness of the ventricular stimulation protocol. Thus, the

Fig. 4.24 Retrograde Activation With Right Ventricular (RV) Septal Pacing. Sinus and RV septal paced complexes (S) are shown. Retrograde atrial activation is concentric, following a retrograde His potential (H'). CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; His_{dist}, distal His bundle; His_{mid}, middle His bundle; His_{prox}, proximal His bundle; HRA, high right atrium; RV_{sept}, RV septum.

stimulation protocol is usually limited to single or double VES in patients without a clinical history consistent with malignant ventricular arrhythmias. The use of high pacing output can also increase the risk of such arrhythmias. Therefore ventricular stimulation at 2× diastolic threshold and 1-millisecond pulse width is preferable.

Normal Response to Rate-Incremental Ventricular Pacing

Ventricular pacing provides information about VA conduction, which is present in 40% to 90% of patients, depending on the population studied. Absence of VA conduction at any paced rate is common and normal. There is no difference in the capability of VA conduction regarding the site of ventricular stimulation in patients with a normal HPS. When present, normal VA conduction uses the normal AV conduction system, with the earliest atrial activation site usually in the septal region in proximity to the AVN. In some cases, the slow posterior AVN pathway is preferentially engaged so that the earliest atrial activation site is somewhat posterior to the AVN, closer to the CS os.

The normal AVN response to rate-incremental ventricular pacing is a gradual delay of VA conduction (manifest as gradual prolongation of the HA interval) as the PCL decreases. Retrograde VA Wenckebach block and a higher degree of block appear at shorter PCLs. Occasionally, VA Wenckebach cycles are terminated with ventricular echo beats secondary to retrograde dual AVN physiology. When a retrograde His potential is visible, a relatively constant VH interval at a rapid pacing rate, despite the development of retrograde VA block, localizes the site of block to the AVN (Fig. 4.25). When a retrograde His potential is not visible during ventricular pacing, the site of VA block, when it occurs,

must be inferred from the effect of paced impulses on conduction of spontaneous or stimulated atrial beats (i.e., by analyzing the level of retrograde concealment; see Fig. 4.25). If the AH interval of the atrial beat is independent of the time relationship of the paced impulse, the site of block is in the HPS (infranodal). On the other hand, if the AH interval varies according to the coupling interval of the atrial beat to the paced QRS, or if the atrial beat fails to depolarize the HB, the site of block is in the AVN. Moreover, drugs that enhance AVN (but not HPS) conduction (e.g., atropine) improve VA conduction if the site of block is in the AVN, but they do not affect VA conduction if the site of block is in the HPS.

At comparable PCLs, anterograde AV conduction is better than retrograde VA conduction in most patients. AVN conduction is the major determinant of retrograde VA conduction. Patients with prolonged PR intervals are much less likely to demonstrate retrograde VA conduction. Furthermore, patients with prolonged AVN conduction are less capable of VA conduction than patients with infranodal conduction delay. Anterograde AV block in the AVN is almost universally associated with retrograde VA block. On the other hand, anterograde AV block in the HPS is associated with some degree of VA conduction in up to 40% of cases. However, the exact comparison between anterograde and retrograde AVN conduction can be limited by the absence of a visible retrograde His potential during ventricular stimulation. Consequently, localization of the exact site of conduction delay or block (AVN vs. HPS) may not be feasible. The response to rate-incremental pacing at two different PCLs may differ because of the opposite effects of the PCL on AVN and HPS refractoriness.

Rapid ventricular pacing can result in ipsilateral retrograde BBB, with subsequent impulse propagation across the septum, retrogradely up the contralateral bundle branch, and then to the HB. Such an event can manifest as sudden prolongation of the VH interval during pacing. This can be followed by resumption of VA conduction after a period of VA block in the AVN when the VH interval is short because the delay in the HPS allows recovery of the AVN (the gap phenomenon). This occurrence can permit better visualization of the His potential, and, by comparing the ventricular electrogram in the HB recording when the His potential is clearly delayed with that with normal retrograde ipsilateral bundle branch conduction, a previously unappreciated His potential within that electrogram can then be visualized (see Fig. 4.25).

To exclude the presence of a nondecremental retrogradely conducting BT, the VES technique is usually more effective than rate-incremental ventricular pacing for demonstrating normal prolongation of the VA interval. If uncertainty continues to exist, adenosine can be extremely helpful, which is much more likely to block AVN conduction than BT.

Normal Response to Ventricular Premature Stimulation

Because a retrograde His potential may not be visible in 15% to 20% of patients during ventricular pacing, evaluation of the HPS, and consequently VA conduction, is often incomplete. In addition, in the absence of a visible His potential during ventricular pacing, the FRP of the HPS (theoretically, the shortest H₁-H₂ interval at any coupling interval) must be approximated by the S₁-H₂ interval (S₁ being the stimulus artifact of the basic drive CL), so that the S₁-H₂ interval approximates the H₁-H₂ interval, but exceeds it by a fixed amount, the S₁-H₁ interval. Retrograde AVN conduction time (H₂-A₂) is best measured from the end of the His potential to the onset of the atrial electrogram on the HB tracing.

Typically, VA conduction proceeds over the RB or LB, and then to the HB, AVN, and atrium. With a progressively premature VES, the initial delay occurs in the HPS, and the most common site of retrograde VA block is in the HPS. Delay or block in the AVN can occur but is less common.

Fig. 4.25 Complete Retrograde Ventricular-Atrial (VA) Block in the Atrioventricular Node (AVN). Three ventricular paced complexes are shown, the first two of which have a clear retrograde His potential (H') and no retrograde atrial activation (sinus rhythm in atria), suggesting the AVN as the site of VA block. However, the site of VA block (AVN vs. His-Purkinje system) following the third ventricular complex is not obvious because there is no His potential visible following that ventricular stimulus. The site of VA block, however, can be inferred from the effect of paced impulses on conduction of the sinus complex after cessation of pacing. The atrial-His bundle (AH) interval of the conducted sinus complex after the last paced ventricular complex is longer than the baseline AH interval (at right), consistent with retrograde penetration of the AVN by the ventricular stimulus (resulting in concealed conduction) and therefore suggesting the AVN as the site of VA block. His_{dist} , Distal His bundle; His_{prox} , proximal His bundle; HRA , high right atrium; RVA , right ventricular apex.

The typical response to VES can be graphically displayed by plotting the S_1 - S_2 interval versus S_2 - H_2 , S_2 - A_2 , and H_2 - A_2 intervals, as well as the S_1 - S_2 interval versus S_1 - H_2 and A_1 - A_2 intervals. At long S_1 - S_2 intervals, no delay occurs in the retrograde conduction (S_2 - A_2). Further shortening of the S_1 - S_2 intervals results in prolongation in the S_2 - A_2 intervals, and localization of the exact site of S_2 - A_2 delay may not be feasible unless a retrograde His potential is visible (Fig. 4.26A and B). During RV pacing, the initial delay usually occurs in retrograde RB conduction. At a critical coupling interval (S_1 - S_2), block in the RB occurs, and retrograde conduction proceeds over the LB. A retrograde His potential (H_2) eventually becomes visible after the ventricular electrogram in the HB recording (see Fig. 4.26D). Once a retrograde His potential is seen, progressive prolongation in the S_2 - H_2 interval (HPS conduction delay) occurs as the S_1 - S_2 interval shortens, and the VA conduction time (S_2 - A_2) is determined by the HPS conduction delay (S_2 - H_2), as demonstrated by parallel S_2 - A_2 and S_2 - H_2 curves. The degree of prolongation of the S_2 - H_2 interval varies, but it can exceed 300 milliseconds.

In patients with preexistent BBB, retrograde block in the same bundle is common. This is suggested by a prolonged VH interval during a constant paced drive CL or late VES from the ventricle ipsilateral to the BBB, so that a retrograde His potential is usually seen after the ventricular electrogram in the HB tracing (see eFig. 4.8).

In most cases, once a retrograde His potential is visible, the S_1 - H_2 curve becomes almost horizontal because the increase in the S_2 - H_2 interval is similar to the decrease in the S_1 - S_2 interval. This response results in a relatively constant input to the AVN (as determined by measuring the S_1 - H_2 interval) and consequently a fixed H_2 - A_2 interval.

Occasionally, the increase in the S_2 - H_2 interval greatly exceeds the decrease in the S_1 - S_2 interval, thus giving rise to an ascending limb on the curve, with a subsequent decrease in the AVN conduction time (H_2 - A_2) because of decreased input to the AVN. As the S_1 - S_2 interval is further shortened, block within the HPS appears, or ventricular ERP is reached.

HPS refractoriness depends markedly on the CL, and shortening of the basic drive CL shortens the FRP and ERP of the HPS and ventricle. The general pattern, however, remains the same, with an almost linear increase in the S_2 - H_2 interval as the S_1 - S_2 interval is shortened. The curves for S_2 - H_2 versus S_1 - S_2 are shifted to the left, and the curves for S_1 - S_2 versus S_1 - H_2 are shifted down.

Repetitive Ventricular Responses

Ventricular stimulation can trigger extra ventricular beats. Those beats can be caused by different mechanisms; the most common are bundle branch reentry (BBR) beats, ventricular echo beats, and intraventricular reentrant beats. Multiple mechanisms may be responsible for repetitive responses in the same patient. Almost always, one of these responses is BBR.

Bundle Branch Reentry Beats

BBR beats are the most common ventricular response and can occur in up to 50% of normal individuals. In patients with normal hearts, BBR is rarely sustained and is usually self-limiting in one or two complexes. The occurrence of nonsustained BBR in patients with or without structural heart disease is not related to the presence of spontaneous ventricular arrhythmias.

eFig. 4.8 His Recordings in the Presence of Right Bundle Branch Block (RBBB). Two right ventricular drive complexes (S_1) and an extrastimulus (S_2) are shown, with a subsequent sinus complex with typical RBBB. Retrograde His activation (H') cannot traverse the blocked right bundle branch and must occur over the left bundle branch following transseptal ventricular activation, resulting in a long S- H' interval. The S- H' interval prolongs further following the extrastimulus (S_2). Of note, S_2 is associated with retrograde ventricular-atrial block in the atrioventricular node. His_{dist} , Distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; HRA , high right atrium; $RVOT$, right ventricular outflow tract.

Fig. 4.26 Normal Response to Progressively Premature Ventricular Stimulation. Following a drive stimulus (S₁) at a cycle length of 600 milliseconds, a progressively premature ventricular extrastimulus (VES; S₂) is delivered from the right ventricular apex (RVA). (A) At a VES coupling interval of 460 milliseconds, retrograde His potential (arrows) is visible just before the local ventricular electrogram on the His bundle (HB) tracing, and ventricular-atrial (VA) conduction is intact. (B) An earlier VES is followed by some delay in VA conduction and prolongation of the His bundle-atrial interval. (C) A short coupled VES is followed by VA block. A retrograde His potential is not clearly visible. (D) An earlier VES is associated with retrograde block in the right bundle branch (RBB), followed by transseptal conduction and retrograde conduction up the left bundle branch (LBB) to the HB (the retrograde His potential is now visible well after the local ventricular electrogram). VA conduction now resumes because of proximal delay (in the His-Purkinje system), allowing distal recovery in the atrioventricular node (the gap phenomenon). (E) Further decrement in the VES coupling interval results in progressive delay in retrograde HPS conduction (and further prolongation of the S₂-H₂ interval), allowing for anterograde recovery of the RBB, so that the impulse can return down the initially blocked RBB, producing a QRS with a typical LBB block pattern (bundle branch reentry beat). (F) A very early VES is followed by ventricular-atrial block secondary to retrograde block in both the RBB and LBB; therefore no His potential is visible. HRA, High right atrium.

The longest refractory periods in the HPS are found most distally, at or near the Purkinje-myocardial junction. This creates a distal gate that inhibits retrograde conduction of early VES. Thus, when an early VES is delivered to the RV apex, the nearby distal gate of the RB can still be refractory. The results are progressive retrograde conduction delay and block occurring in the distal RB, with subsequent transseptal conduction of the impulse to the LV, leading to retrograde conduction up the LB to the HB (see Fig. 4.26D). At this point, the His potential usually follows the local ventricular electrogram in the HB recording, and retrograde atrial stimulation, if present, follows the His potential. Further decrease in the VES coupling interval produces progressive delay in retrograde HPS conduction. When a critical degree of HPS delay (S_2 - H_2) is attained, the impulse can return down the initially blocked RB, thus producing a QRS with a typical LBBB pattern and left-axis deviation, because ventricular activation originates solely from conduction over the RB (see Fig. 4.26E). This beat is called a BBR beat or V_3 phenomenon.

The HV interval of the BBR beat usually approximates that during anterograde conduction. However, it can be shorter or longer, depending on the site of HB recording relative to the turnaround point and on anterograde conduction delay down the RB.

Ventricular Echo Beats

This is the second most common response and can occur in 15% to 30% of normal individuals. It is caused by reentry in the AVN, and it appears when a critical degree of retrograde AVN delay is achieved. These patients have retrograde dual AVN physiology, and the last paced beat conducts slowly retrogradely up the slow AVN pathway and then anterogradely down the fast pathway to produce the echo beat (eFig. 4.9). In most cases, this delay is achieved before the appearance of a retrograde His potential beyond the local ventricular electrogram. At a critical H_2 - A_2 interval (or V_2 - A_2 interval, when the His potential cannot be seen), an extra beat with a normal anterograde QRS morphology results. Atrial activity also precedes the His potential before the echo beat.

This phenomenon can occur at long or short coupling intervals and depends only on the degree of retrograde AVN conduction delay. The presence of block within the HPS prevents its occurrence, as does block within the AVN. If a retrograde His potential can be seen throughout the zone of coupling intervals, a reciprocal relationship between the H_2 - A_2 and A_2 - H_3 intervals can often be noted.

Intraventricular Reentrant Beats

This response usually occurs in the setting of a cardiac pathological condition, especially coronary artery disease with a prior myocardial infarction (MI). It usually occurs at short coupling intervals and can have any morphology, but more often RBBB than LBBB in patients with a prior MI. Such beats occur in fewer than 15% of normal patients with a single VES at $2\times$ diastolic threshold and in 24% with double VESs. In contrast, intraventricular reentrant beats occur following single or double VESs in 70% to 75% of patients with prior VT or VF and cardiac disease. The incidence of this response increases with increasing the number of VESs, basic drive CLs, and stimulation sites used. These responses are usually nonsustained (1 to 30 complexes) and typically polymorphic. In patients without prior clinical arrhythmias, such responses are of no clinical significance.

MISCELLANEOUS ELECTROPHYSIOLOGICAL PHENOMENA

Concealed Conduction

Concealed conduction can be defined as the propagation of an impulse within the specialized conduction system of the heart that can be

recognized only from its effect on the subsequent impulse, interval, or cycle. This phenomenon can occur in any portion of the AV conduction system.

As long as the cardiac impulse is traveling in the specialized conduction system, the amount of electrical current generated is too small to be recorded on the surface ECG. However, if this impulse travels only a limited distance—incomplete anterograde or retrograde penetration—within the system, it can interfere with the formation or propagation of another impulse. When this interference can be recognized in the tracing because of an unexpected behavior of the subsequent impulse, unexpected in the sense that the event cannot be explained on the basis of readily apparent physiological or pathophysiological processes, it is known as concealed conduction.

The effect on subsequent events is an important part of the definition of concealed conduction because it differentiates the concept of concealed conduction from other forms of incomplete conduction, such as block of conduction at the level of the AVN or HPS. Ideally, a diagnosis of concealed conduction is supported by evidence in other areas of the same tracing where, given the opportunity and proper physiological setting, an impulse that is occasionally concealed can be conducted and become manifest. However, this condition cannot always be satisfied, nor is it absolutely necessary for the diagnosis of concealed conduction. Following are descriptions of the most frequent clinical circumstances in which concealed conduction can be observed.

Ventricular Response During Atrial Fibrillation

Repetitive concealed conduction is the mechanism of a slow and irregular ventricular rate during AF, with varying degrees of atrial penetration into the AVN. During AF, the irregular ventricular response is caused by the varying depth of penetration of the numerous atrial wavefronts approaching the AVN. Although the AVN would be expected to conduct whenever it recovers excitability after the last conducted atrial impulse, which would then be at regular intervals, the ventricular response is irregularly irregular because some fibrillatory impulses penetrate the AVN incompletely and block, thus leaving it refractory in the presence of subsequent atrial impulses.

Unexpected Prolongation or Failure of Conduction

Prolongation of the PR (and AH) interval or AVN block can occur secondary to a nonconducted premature depolarization of any origin (atrium, ventricle, or HB). The premature impulse incompletely penetrates the AVN (anterogradely or retrogradely), resets its refractoriness, and renders it fully or partially refractory at the time of the next sinus beat, which may then be blocked or may conduct with longer PR interval (see Fig. 4.25). For example, concealed junctional (HB) impulses can manifest as isolated PR interval prolongation, pseudo-type I AV block, or pseudo-type II AV block. ECG clues to concealed junctional extrasystoles causing such unexpected events include abrupt unexplained prolongation of the PR interval, the presence of apparent type II AV block in the presence of a normal QRS, the presence of types I and II AV block in the same tracing, and the presence of manifest junctional extrasystoles elsewhere in the tracing.

Unexpected Facilitation of Conduction

When a premature impulse penetrates the AV conduction system, it can result in facilitation of AV conduction and normalization of a previously present AV block or BBB by one of two mechanisms: (1) pre-exciting parts of the conduction system so that its refractory period ends earlier than expected (i.e., peeling back the refractory period of that tissue, thus allowing more time to recover excitability), or (2) causing CL-dependent shortening of refractoriness of tissues (i.e., atria, HPS, and ventricles) by decreasing the CL preceding the subsequent

eFig. 4.9 Retrograde Dual Atrioventricular Pathways. Fixed-rate ventricular pacing results in retrograde conduction; retrograde His potential is labeled H'. The first three complexes are conducted over a fast atrioventricular nodal (AVN) pathway; with the fourth complex, the fast AVN pathway conduction is blocked and retrograde conduction proceeds up the slow pathway (longer ventricular-atrial interval), followed by a fused QRS complex, partially paced and partially conducted to the His bundle anterogradely over the fast pathway. The two AVN pathways have different earliest atrial activation sites, indicated by colored arrows and dashed lines. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; His_{dist}, distal His bundle; His_{prox}, proximal His bundle; HRA, high right atrium; RVOT, right ventricular outflow tract.

spontaneous impulse. Abrupt normalization of the aberration by a PVC, the finding of which proves retrograde concealment as the mechanism for perpetuation of aberration, is based on these principles.

Perpetuation of Aberrant Conduction During Supraventricular Tachycardias

The most common mechanism (70%) of perpetuation of aberrant conduction during tachyarrhythmias is retrograde penetration of the blocked bundle branch subsequent to transseptal conduction. For example, a PVC from the LV during an SVT can activate the LB early and then conduct transseptally and later penetrate the RB retrogradely. Subsequently, the LB recovers in time for the next SVT impulse, whereas the RB remains refractory. Therefore the next SVT impulse travels to the LV over the LB (with an RBBB pattern, phase 3 aberration). Conduction subsequently propagates from the LV across the septum to the RV. By this time, the distal RB has recovered, thereby allowing retrograde penetration of the RB by the transseptal wavefront and rendering the RB refractory to each subsequent SVT impulse (see Fig. 10.8). This scenario is repeated and RBBB continues until another, well-timed PVC preexcites the RB (and either peels back or shortens its refractoriness), so that the next impulse from above finds the RB fully recovered and conducts without aberration (see Fig. 10.4). This phenomenon may persist even when the PCL is prolonged, until the site of collision in

the affected bundle branch has recovered adequately for anterograde propagation (Fig. 4.27).

Gap Phenomenon

The term *gap* in AVN conduction was originally used to define a zone in the cardiac cycle during which PACs failed to evoke ventricular responses, whereas PACs of greater or lesser prematurity conducted to the ventricles. The physiological basis of the gap phenomenon depends on a distal area with a long refractory period and a proximal site with a shorter refractory period. During the gap phenomenon, initial block occurs distally. With earlier impulses, proximal conduction delay is encountered, which allows the distal site of early block to recover excitability and resume conduction.

The gap phenomenon is not an abnormality, but reflects the interplay between conduction velocity and refractory periods at two different levels in the AV conduction system. Demonstration of the gap phenomenon can be enhanced or eliminated by any intervention that alters the relationship between the EP properties of those structures (e.g., changes in the neurohumoral tone created by drugs or changes in the heart rate by pacing).

An example of the most common type of gap phenomenon is an AES (A_2) conducting with modest delay through the AVN that finds the HB still refractory, thus causing block. With increasing prematurity

Fig. 4.27 Perpetuation of Concealed Conduction in the Left Bundle Branch (LB). Segments of a continuous run of atrial pacing are shown, starting at 490 milliseconds (A). At 480 milliseconds pacing cycle length (PCL), LB block develops (red numbers) and persists despite gradually increasing the PCL to 500 milliseconds (B), 550 milliseconds (C), 600 milliseconds (D) and 650 milliseconds (E) (blue numbers). Finally, at 660 milliseconds (E), the site of block in the LB has migrated distally enough that conduction in the LB can resume. This is an extreme example of linking or concealed perpetuation of block, over a range of PCLs of 180 milliseconds. *His_{dist}*, Distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RV*, right ventricular.

of the AES, the AES travels more slowly through the AVN (i.e., the A_2 - H_2 interval prolongs further), so that the H_1 - H_2 interval now exceeds the refractory period of the HB. By the time the impulse traverses the AVN, the HB has completed its ERP and conduction resumes (Fig. 4.28).

Other types of the gap phenomenon are described in which the required conduction delay is in the HB, proximal AVN, or atria. The gap phenomenon depends on the relationship between the EP properties of two sites; any pair of structures in the AV conduction system that has the appropriate physiological relationship can exhibit the gap phenomenon (e.g., AVN-HB, HB-HPS, atrium-AVN, atrium-HPS, proximal AVN-distal AVN, proximal HPS-distal HPS), and gap can occur during anterograde or retrograde stimulation. Therefore there are almost endless possibilities for gaps, all based on the fundamental precept of “proximal delay allows distal recovery” (see Fig. 4.26C and D).

Supernormality

Supernormal conduction implies conduction that is better than anticipated or conduction that occurs when block is expected. Electrocardiographically, however, supernormal conduction is not better than normal conduction, only better than expected. When an alteration in conduction can be explained in terms of known physiological events, true supernormal conduction need not be invoked.⁶⁴

Fig. 4.28 Anterograde Atrioventricular (AV) Gap Phenomenon. (A) An atrial extrastimulus (AES; A_2) conducting with modest delay through the atrioventricular node (AVN) finds the His bundle (HB) still refractory, causing atrioventricular block. (B) An earlier AES results in further prolongation of the A_2 - H_2 interval and the subsequent H_1 - H_2 interval (shaded area). The longer H_1 - H_2 interval now exceeds the refractory period of the HB, and, by the time the impulse traverses the AVN, the HB has completed its effective refractory period and conduction resumes; however, the conducted QRS has a left bundle branch block morphology and a longer HV interval because the left bundle is still refractory. HRA, High right atrium.

Supernormal conduction is dependent on supernormal excitability, a condition that exists during a brief period of repolarization, at the end of phase 3. During the supernormal period, excitation is possible in response to an otherwise subthreshold stimulus; that same stimulus fails to elicit a response earlier or later than the supernormal period. Two factors are responsible for supernormality: the availability of fast Na^+ channels and the proximity of the membrane potential to threshold potential. During the supernormal phase of excitability, the cell has recovered enough to respond to a stimulus. However, because the membrane potential is still reduced, it requires only a little additional depolarization to bring the fiber to threshold; thus, a smaller stimulus than is normally required elicits an action potential. Supernormality has been demonstrated in the HPS, Bachmann's bundle in the dog, and working myocardium of the atrium and ventricle, but not in the AVN.⁶⁴

Supernormal excitability is diagnosed when the myocardium responds to a stimulus that is ineffective when applied earlier or later in the cycle. Some ECG manifestations of supernormality include the following:

1. Paradoxical normalization of bundle branch conduction at an R-R interval shorter than that associated with BBB. This can occur with a PAC conducting with a normal QRS during baseline NSR with BBB or with acceleration-dependent BBB that normalizes at even faster rates.
2. Intermittent AV conduction during periods of high-degree AV block. Only the P waves falling on or just after the terminal part of the T wave are conducted, whereas other timed P waves fail to conduct.
3. A poorly sensing pacemaker captures just at the end of the T wave, but not elsewhere in the cardiac cycle.

Although supernormal conduction is a proven property of the HPS and has been demonstrated in vitro, it is uncertain whether true supernormal conduction is a clinically important phenomenon. Other physiological mechanisms can be invoked to explain almost all reported examples of supernormal conduction in humans. Causes of apparent or pseudo-supernormal conduction include the gap phenomenon (the most common mechanism of pseudo-supernormal conduction), peeling back of refractoriness, shortening of refractoriness by changing the preceding CL, Wenckebach phenomena in the bundle branches, bradycardia-dependent (phase 4) block, summation, dual AVN physiology, reentry with ventricular echo beats, and concealed junctional extrasystoles.^{64,65}

COMPLICATIONS OF ELECTROPHYSIOLOGICAL TESTING

Risks and Complications

The complication rate of EP testing is relatively low (less than that of coronary arteriography) when only right-heart catheterization is performed, with almost negligible mortality. The risk of complications increases significantly in patients with severe or decompensated cardiac disease. The addition of left-heart access or therapeutic maneuvers (e.g., ablation) to the procedure increases the incidence of complications, especially with the increasing use of extensive ablation to treat AF and ischemic VT.

Complications of EP testing include vascular injury (hematoma, pseudoaneurysm, and arteriovenous fistula), bleeding requiring transfusion, deep venous thrombosis and pulmonary embolism, systemic thromboembolism, infection at catheter sites, systemic infection, pneumothorax, hemothorax, pericarditis, cardiac perforation and tamponade, MI, worsening heart failure, stroke, complete AV block, and BBB. Although potentially lethal arrhythmias such as rapid VT or VF can occur in the EP laboratory, they are not necessarily regarded as complications, but are often expected and anticipated. Complications following specific ablation procedures are discussed in subsequent chapters.

Iatrogenic Problems Encountered During Electrophysiological Testing

Mechanical irritation from catheters during placement inside the heart, even when they are not being manipulated, can cause arrhythmias and conduction disturbances, including induction of atrial, junctional, and ventricular ectopic beats or tachyarrhythmias, AV block, and BBB. AV block can occur especially during RV catheterization in patients with preexisting LBBB, and occasionally secondary to mechanical trauma of the compact AVN. Ventricular stimulation can also occur from physical movement of the ventricular catheter coincident with atrial contraction, thus producing patterns of ventricular preexcitation on the surface ECG. Recognition of all these iatrogenic patterns is important for avoiding misinterpretation of EP phenomena and determining the significance of findings in the laboratory.

AF and VF are to be avoided unless they are the subject of the study. AF obviously does not permit study of any other form of SVT, and VF requires prompt defibrillation. If AF must be initiated for diagnostic purposes (e.g., to assess ventricular response over an AV BT), it is preferably induced at the end of the diagnostic portion of the study. Patients with a prior history of AF are more prone to the occurrence of sustained AF in the EP laboratory. Frequently, this occurs during initial placement of catheters; excessive manipulation of catheters in the atria should therefore be avoided.

Another iatrogenic problem is catheter trauma resulting in abolition of BT conduction or injury to the focus of a tachycardia or to the reentrant pathway, which can make the mapping and curative ablation difficult or impossible.

VIDEOS

The following videos accompany this chapter:

Video 4.1 Placement of the Coronary Sinus Catheter via the Inferior Vena Cava (IVC): Fluoroscopy. Simultaneous left anterior oblique (LAO) and right anterior oblique (RAO) fluoroscopy projections are acquired during catheterization of the coronary sinus (CS) via the IVC. Electrophysiological (EP) catheter are positioned in the right atrial (RA) appendage, right ventricular (RV) apex, and at the His bundle (HB) region. The CS catheter is advanced via the IVC. The tip of the catheter is first placed into the RV, using the RAO fluoroscopy view, and flexed downward toward the RV inferior wall. Subsequently, the catheter is withdrawn until it lies at the inferoseptal aspect of the tricuspid annulus. Using the LAO or RAO view, the catheter is then withdrawn gently with clockwise rotation until the tip of the catheter drops into the CS ostium (CS os). Afterward, the catheter is advanced into the CS concomitantly with gradual release of the catheter curve.

Video 4.2 Transaortic Left Ventricular (LV) Access. Fluoroscopy. Simultaneous left anterior oblique (LAO) and right anterior oblique (RAO) fluoroscopy projections are acquired during retrograde LV access. Leads of an implantable cardioverter-defibrillator (ICD) are visualized in the right atrial (RA) appendage and right ventricular (RV) apex. A multipolar electrophysiological (EP) catheter is positioned at the His bundle (HB) region. The ablation catheter is initially advanced to the descending aorta, where a tight J curve is formed with the catheter tip before passage to the aortic root to minimize catheter manipulation in the arch. The curved catheter is advanced through the aortic valve. A long vascular sheath is used in this case to provide added catheter stability during LV mapping.

Video 4.3 Atrial Transseptal Puncture: Guided by Fluoroscopy. Simultaneous left anterior oblique (LAO) right anterior oblique (RAO) fluoroscopy projections are acquired during atrial septal puncture. Initially, the sheath-dilator-needle assembly is visualized in the superior vena cava (SVC), with curves of the dilator, sheath, and needle aligned so that they are all in agreement, the Brockenbrough needle tip positioned within 1 to 2 cm of the dilator tip, and the assembly rotated leftward and posteriorly. Also visualized are an electrophysiological (EP) catheter positioned at the His bundle (HB) region (to mark the root of the aorta), an intracardiac echocardiography (ICE) catheter positioned in the mid right atrium (RA), and a guidewire in the SVC. The assembly is retracted caudally as a single unit (while maintaining the relative positions of its components). Note that, in the LAO view, the dilator tip moves slightly leftward upon entering the RA and then leftward again while descending below the aortic root. A third abrupt leftward movement ("jump") at the level of the HB region (marked by an EP catheter) indicates passage over the limbus into the fossa ovalis. This latter jump generally occurs at the level of the HB region. In the RAO view, the dilator tip is directed posteriorly to the His bundle region. Once the dilator tip is confirmed at the fossa ovalis, the needle is extended across the interatrial septum. A 0.014 angioplasty wire is advanced through the Brockenbrough needle into the LA. Initially, the wire coils at the LA roof. The wire is then withdrawn and advanced into the left superior pulmonary vein, as it is visualized extending outside the cardiac silhouette. The sheath-dilator assembly is advanced as a single unit over the needle and angioplasty wire into the LA, while holding the needle in a stable position. Subsequently, the sheath is advanced over the dilator while holding the needle and dilator in a stable position. Note that some resistance at the interatrial septum meets advancing the sheath over dilator, and force build-up causes a sudden jump of the dilator-sheath assembly toward the LA lateral wall. Having the angioplasty wire deeply seated in a left-sided pulmonary vein helps direct the path of the assembly as it enters the LA and minimizes the risk of inadvertent injury to the opposing LA wall. A second atrial septal puncture is performed using the same technique for the first puncture. A lasso catheter is positioned in the LA at the ostium of the left superior pulmonary vein (PV). Again, advancing the sheath across the septum is met by resistance and causes a jump of the sheath-dilator assembly, which is controlled and directed in a safe path over the guidewire.

Video 4.4 Atrial Transseptal Puncture: Guided by Intracardiac Echocardiography (ICE). The interatrial septum is visualized by the ICE phased array catheter positioned in the mid-right atrium. As demonstrated, the optimal ICE image to guide transseptal puncture will demonstrate adequate space behind the interatrial septum on the left atrial (LA) side, but will not include the aortic root because it would be too anterior for the interatrial septum to be punctured safely. Advancement of sheath-dilator-needle assembly against the interatrial septum causes tenting of the septum. The Brockenbrough needle is then advanced while saline is infused continuously through the needle. With successful transseptal puncture, sudden collapse of the tented fossa is observed, and saline infusion through the needle is visualized on ICE as bubbles in the LA.

Video 4.7 Atrial Transseptal Puncture (in the Presence of Atrial Septal Defect Closure Device [ASD]). Fluoroscopic images are shown in the left anterior oblique projection are acquired during atrial septal puncture in a patient with prior device closure of an atrial septal defect. Initially, the needle is erroneously advanced within the inferior portion of the device, and the closure device is observed on fluoroscopy to be pushed by the needle as it is advanced across the atrial septum. While a 0.014 angioplasty wire could be advanced through the Brockenbrough needle into the left atrium (LA), the dilator and sheath could not be advanced across the device. Then, the needle was withdrawn out of the LA, and a site on the atrial septum more caudal and posterior to the closure device was successfully punctured. CS, Coronary sinus catheter.

Video 4.5 Atrial Transseptal Puncture: Guided by Transesophageal Echocardiography. The left atrium (LA) is visualized on top, and the right atrium (RA) is visualized at 7 o'clock. Advancement of the sheath-dilator-needle assembly against the interatrial septum causes tenting of the septum. The Brockenbrough needle is then advanced while saline is infused continuously through the needle. Bubbles of saline infusion are visualized in the LA once the needle tip crosses the septum. AoV, Aortic valve.

Video 4.8 Pericardial Access: Technique. Initially, catheters are positioned in the coronary sinus (CS), right ventricular apex (RVA), and the His bundle (HB) region through the femoral approach. The leads of a dual-chamber implantable cardioverter-defibrillator are visualized in the right atrial appendage (RAA) and RVA. The puncture needle is introduced at the angle between the left border of the subxiphoid process and the lower left rib, with the needle pointing to the left shoulder. The needle is then advanced under fluoroscopy guidance until close to the cardiac silhouette, and then a small amount of contrast is injected through the needle to assess the relation of the needle to the parietal pericardium. Once tenting of the pericardium is seen, a slight advance achieves entry into the pericardial space. When the needle reaches the pericardial sac, injected contrast will spread around the heart, restricted to its silhouette. After reaching the pericardial space, a long soft J tip guide wire is advanced far enough to silhouette the pericardial space. The puncture needle is then withdrawn and an 8 Fr dilator is advanced over the guide wire under fluoroscopic guidance for pre-dilatation, followed by insertion of a standard 8 Fr sheath.

Video 4.6 Atrial Transseptal Puncture Using the Radiofrequency (RF)-Powered Needle. The tip of the needle can be easily visualized on fluoroscopy (both inside or outside the dilator) and intracardiac echocardiography (ICE). Once septal tenting is observed on ICE, RF energy is delivered to the blunt, closed tip of the needle, resulting in steam popping and septal perforation.

Cardiac mapping refers to the process of identifying the temporal and spatial distributions of myocardial electrical potentials during a particular heart rhythm. Cardiac mapping is a broad term that covers several modes of mapping such as body surface, endocardial, and epicardial mapping, in order to characterize the timing and/or amplitude (voltage) of signals relative to each other. Mapping during tachycardia aims at elucidation of the mechanism or mechanisms of the tachycardia, description of the propagation of activation from its initiation to its completion within a region of interest, and identification of the site of origin or a critical site of conduction to serve as a target for catheter ablation.

ACTIVATION MAPPING

Fundamental Concepts

Essential to the effective management of any cardiac arrhythmia is a thorough understanding of the mechanisms of its initiation and maintenance. Conventionally this has been achieved by careful study of the surface electrocardiogram (ECG) and correlation of the changes therein with data from intracardiac electrograms recorded by catheters at various key locations within the cardiac chambers (i.e., activation mapping). A record of these electrograms documenting multiple sites simultaneously is studied to determine the mechanisms of an arrhythmic event.

The main value of intracardiac and surface ECG tracings consists of the comparative timing of electrical events and the determination of the location and direction of impulse propagation. In addition, electrogram morphology can be of significant importance during mapping. Establishing electrogram criteria, which permit accurate determination of the moment of myocardial activation at the recording electrode, is critical for the construction of an area map of the activation sequence. Bipolar recordings are generally used for activation mapping. Unipolar recordings are used to supplement the information obtained from bipolar recordings.¹

Unipolar Recordings

Timing of local activation. The major component of the unipolar electrogram allows for the determination of the local activation time, although there are exceptions. The point of maximum amplitude, the zero crossing, the point of maximum slope (maximum first derivative),

and the minimum second derivative of the electrogram have been proposed as indicators of underlying myocardial activation (Fig. 5.1). The maximum downslope (i.e., maximum change in potential, dV/dt) of the unipolar electrogram coincides best with the arrival of the depolarization wavefront directly beneath the electrode and is now considered the most accurate marker of local tissue activation. Using this fiducial point, errors in determining the local activation time as compared with intracellular recordings have typically been less than 1 millisecond. This is true for filtered and unfiltered unipolar electrograms.¹⁻⁴

Direction of local activation. The morphology of the unfiltered unipolar recording indicates the direction of wavefront propagation. By convention, the mapping electrode that is in contact with the myocardium is connected to the positive input of the recording amplifier. In this configuration, positive deflections (R waves) are generated by propagation *toward* the recording electrode, and negative deflections (QS complexes) are generated by propagation *away* from the electrode (Figs. 5.2 and 5.3). If a recording electrode is at the source from which all wavefronts propagate (at the site of initial activation), depolarization will produce a wavefront that spreads away from the electrode, thus generating a monophasic QS complex.

It is important to recognize that a QS complex can be recorded when the mapping electrode is floating in the cavity and not in contact with the myocardium. In that situation, the initial negative slope of the recording is typically slow, suggesting that the electrogram is a far-field signal, generated by tissue at some distance from the recording electrode.

Filtering at higher corner frequencies (e.g., 30 Hz) alters the morphology of the signal, so that the morphology of the unipolar electrogram is no longer indicative of the direction of wavefront propagation, and the presence or absence of a QS complex cannot be used to infer proximity to the site of earliest activation (Fig. 5.4).^{1,5}

Advantages of unipolar recordings. One important value of unipolar recordings is that they provide a more precise measurement of the timing of local activation. This is true for filtered and unfiltered unipolar electrograms. In addition, unfiltered unipolar recordings provide information about the direction of impulse propagation. Furthermore, unipolar recordings allow pacing and recording at the same location while eliminating a possible anodal contribution to depolarization that is sometimes seen with bipolar pacing at high output. This generally facilitates the use of other mapping modalities—namely pace mapping.^{1,2,5}

Fig. 5.1 Unipolar Electrogram Activation Times. A lead II electrocardiogram and a unipolar electrogram (Egm) from the ventricle of a patient with Wolff-Parkinson-White syndrome are shown. The vertical dashed line denotes the onset of the delta wave; the horizontal dotted line is the baseline of the unipolar recording. Several candidates for the timing of unipolar activation are labeled with corresponding activation times relative to delta wave onset.

Fig. 5.2 Hypothetical Recordings From a Multipolar Electrode Catheter. (A) The electrodes are near a point source of activation (red dot in center of concentric rings). Note the timing and shape of the resultant electrogram patterns based on distance from point source, unipolar or bipolar recording, and width of bipole. (B) The tip electrode (1) is at the point source of activation. Note the differences in timing and shape of the electrograms compared with A.

Disadvantages of unipolar recordings. The major disadvantage of unipolar recordings is that they have poor signal-to-noise ratio and contain substantial far-field signal generated by depolarization of tissue remote from the recording electrode. Therefore distant activity can be difficult to separate from local activity. This is especially true when

Fig. 5.3 Unipolar and Bipolar Recordings From a Patient With Wolff-Parkinson-White Syndrome. The dashed line denotes the onset of the QRS complex (delta wave). *Right panel*, Recordings at the successful ablation site, characterized by QS in the unipolar recording. The most rapid component precedes the delta wave onset by 22 milliseconds, has the same timing as the peak of the ablation distal electrode recording, and precedes the ablation proximal electrode recording (arrows). *Left panel*, Recordings from a poorer site, with an rS in the unipolar recording; most of the bipolar recordings are atrial. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *Abl_{uni}*, unipolar ablation; *HRA*, high right atrium; *RV*, right ventricle.

recording from areas of prior myocardial infarction (MI), where the fractionated ventricular potentials are ubiquitous, and it is often impossible to select a rapid negative dV/dt when the entire QS potential is slowly inscribed—that is, cavity potential. Furthermore, a QS electrogram configuration has a low spatial resolution and relatively low specificity, being attainable in an area of more than 1 cm in diameter from the real site of origin of the arrhythmia or when the exploring electrode has poor contact with the myocardium.⁶ Another disadvantage is the inability to record an undisturbed electrogram during or immediately after pacing. This is a significant disadvantage when entrainment mapping is to be performed during activation mapping because the recording of the return tachycardia complex on the pacing electrode immediately after cessation of pacing is required to interpret entrainment mapping results. There is also some baseline drift of the unipolar recording in some recording systems that makes interpretation difficult.^{1,5,7}

Bipolar Recordings

Timing of local activation. Algorithms for detecting local activation time from bipolar electrograms have been more problematic, partly because of generation of the bipolar electrogram by two spatially separated recording poles. In a homogeneous sheet of tissue, the initial peak of a filtered (30 to 300 Hz) bipolar signal coincides with depolarization beneath the recording electrode and appears to correlate most consistently with local activation time, corresponding to the maximal negative dV/dt of the unipolar recording (see Fig. 5.3).

A bipolar electrogram is the sum of two unipolar electrograms with a time delay due to the interelectrode distance. When a bipolar electrogram with an interelectrode distance is recorded in a homogeneous sheet of tissue, activation time delay between the two poles is usually minimal. In the setting of inhomogeneous conduction, however, a significant time delay can exist between two unipolar electrograms, resulting in a fractionated electrogram when converted to a bipolar electrogram (Figs. 5.5 and 5.6).⁸

Fig. 5.4 Effect of Filtering on Intracardiac Recordings. The signal labeled “Bipolar 30–500 Hz” is the same signal as the proximal His bundle signal (His_{prox}) above it, displayed at lower gain. All signals beneath this are of the same gain but different filter bandwidths, and they illustrate progressive loss of signal amplitude as the bandwidth is narrowed. Unipolar signals below are of the same gain.

In the setting of complex multicomponent bipolar electrograms, such as those with marked fractionation and prolonged duration seen in regions with complex conduction patterns (e.g., in regions of slow conduction in macroreentrant atrial tachycardia [AT] or ventricular tachycardia [VT]), determination of local activation time becomes challenging, and the decision about which activation time is most appropriate needs to be made in the context of the particular rhythm being mapped. Therefore, during mapping procedures, the onset (rather than the peak or nadir) of high-frequency components of a local bipolar electrogram is often used because it is easier to determine reproducibly, especially when measuring heavily fractionated, low-amplitude local electrograms. The onset of the bipolar electrogram likely precedes the maximal $-dV/dt$ in unipolar electrogram by 15 to 30 milliseconds.³

To acquire true local electrical activity, a bipolar electrogram with an interelectrode distance of less than 1 cm is desirable. Smaller interelectrode distances record increasingly local events (as opposed to far-field). Elimination of far-field noise is usually accomplished by filtering the intracardiac electrograms, typically at 30 to 500 Hz.^{1,5,6}

Direction of local activation. The morphology and amplitude of bipolar electrograms are influenced by many factors, including (1) the orientation of the bipolar recording axis to the direction of propagation of the activation wavefront; (2) electrode size; (3) interelectrode distance; (4) electrode-tissue contact (i.e., the distance between the source of the

potential and the recording electrode); (5) anisotropic conduction; and (6) intrinsic characteristics of the recorded medium (e.g., normal myocardial tissue versus scar). A wavefront that is propagating in the direction exactly perpendicular to the axis of the recording dipole produces no difference in potential between the electrodes and hence no signal.^{2,5}

Although the direction of wavefront propagation cannot be reliably inferred from the morphology of the bipolar signal, a change in morphology can provide important clues about the activation pattern of the propagating wavefront. The change in polarity in bipolar electrograms recorded across an ablation line is consistent with complete line conduction block. For example, when recording from the lateral aspect of the cavotricuspid isthmus (CTI) during pacing from the coronary sinus (CS), a reversal in the bipolar electrogram polarity from positive to negative at the ablation line indicates complete isthmus block. Similarly, if bipolar recordings are obtained with the same catheter orientation parallel to the atrioventricular (AV) annulus during retrograde bypass tract (BT) conduction, an RS configuration electrogram will be present on one side of the BT, where the wavefront is propagating from the distal electrode toward the proximal electrode, and a QR morphology electrogram will be present on the other side, where the wavefront is propagating from the proximal electrode toward the distal electrode (eFig. 5.1).^{1,5}

Furthermore, the “bipolar” electrogram can be considered as a “mini-unipolar” recording with the proximal electrode simulating the indifferent remote electrode in the unipolar electrogram configuration, and thus the bipolar electrogram morphology may also be helpful in localizing the site of origin of focal arrhythmias. Hence, when the distal electrode of the mapping catheter is positioned at the site of origin of a focal tachycardia (e.g., premature ventricular contractions [PVCs]), an early negative deflection in the initial component of the bipolar electrogram reflects the wavefront propagation opposite to the recording dipole vector (i.e., depolarization reaches electrode 1 before electrode 2). A recent report found that a negative concordance in the initial forces of both unipolar and bipolar electrograms (in addition to the electrogram temporal relationship assessment) may be considered a reliable criterion to identify the site of origin of focal ventricular arrhythmias.^{2,6}

Advantages of bipolar recordings. Bipolar recordings provide an improved signal-to-noise ratio. In addition, high-frequency components are more accurately seen, which facilitates the identification of local depolarization, especially in abnormal areas of infarction or scar.^{2,5}

Disadvantages of bipolar recordings. In contrast to unipolar signals, the direction of wavefront propagation cannot be reliably inferred from the morphology of a single bipolar signal; however, with two adjacent bipolar recordings, the recording that occurs first is closer to the wavefront source. Furthermore, bipolar recordings do not allow simultaneous pacing and recording from the same location. To pace and record simultaneously in bipolar fashion at endocardial sites as close together as possible, electrodes 1 and 3 of the mapping catheter are used for bipolar pacing, and electrodes 2 and 4 are used for recording. The precision of locating the source of a particular electrical signal depends on the distance between the recording electrodes, because the signal of interest can be beneath the distal or proximal electrode (or both) of the recording pair.^{2,5}

Mapping Procedure

Several factors are important for the success of activation mapping, including inducibility of tachycardia at the time of electrophysiology (EP) testing, hemodynamic stability of the tachycardia, and stable tachycardia morphology. In addition, determinations of an electrical reference point, of the mechanism of the tachycardia (focal vs. macroreentrant), and subsequently of the goal of mapping are essential prerequisites.

eFig. 5.1 Recordings From a Patient With a Left Lateral Bypass Tract During Orthodromic Atrioventricular Reentrant Tachycardia. Note electrogram inversion at the middle of the coronary sinus (CS) (arrows), where the earliest retrograde atrial activation (over the bypass tract) occurs (dashed line). CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; His_{dist}, distal His bundle; His_{mid}, middle His bundle; His_{prox}, proximal His bundle; HRA, high right atrium; RV, right ventricle.

Fig. 5.5 Fractionation in Bipolar Electrograms (EGMs). A depolarizing wavefront travels from electrode 1 to electrode 2, which are separated by an interelectrode distance of 2 mm. (A) The wavefront passes the electrodes with a time delay of 2 milliseconds, which results in a simple bipolar EGM. (B) The time delay is increased to 17 milliseconds due to either increased electrode spacing or decreased velocity of the wavefront. This results in an extra negative and increased positive bipolar deflections. (C) Example of two real unipolar EGMs recorded during atrial fibrillation by electrodes with a diameter of 0.45 mm and 2-mm interelectrode spacing and filtered from 0.5 to 400 Hz. The time delay is 12 milliseconds, and conversion to a bipolar EGM gives rise to a fractionated EGM. (From van der Does LJME, de Groot NMS. Inhomogeneity and complexity in defining fractionated electrograms. *Heart Rhythm*. 2017;14:616–624.)

Selection of the Electrical Reference Point

Local activation times must be relative to some external and consistent fiducial marker (such as the onset of the P wave or QRS complex on the surface ECG) or a reference intracardiac electrode. For VT, the QRS complex onset should be assessed using all surface ECG leads to search for the lead with the earliest QRS onset. This lead should then be used for subsequent activation mapping. Similarly, the P wave during AT should be assessed using multiple ECG leads, choosing the one with the earliest P onset. However, determining the onset of the P wave can be impossible if the preceding T wave or QRS is superimposed. To facilitate visualization of the P wave, a ventricular extrastimulus (VES) or a train of ventricular pacing can be delivered to anticipate ventricular activation and repolarization and permit careful distinction of the P wave onset (Fig. 5.7). After determining P wave onset, a surrogate marker, such as right atrial (RA) or CS electrogram indexed to the P wave onset, where it is clearly seen, can be used rather than the P wave onset.

Defining the Goal of Mapping

Determination of the mechanism of the tachycardia (focal vs. macroreentrant) is essential to define the goal of activation mapping. For

focal tachycardias, activation mapping entails localizing the site of origin of the tachycardia focus. This is reflected by the earliest presystolic activity that precedes the onset of the P wave (during focal AT) or QRS (during focal VT) by an average of 10 to 40 milliseconds because only this short amount of time is required after the focus discharges to activate enough myocardium and begin generating a P wave or QRS complex (Fig. 5.8). For mapping macroreentrant tachycardias, the goal of mapping is identification of the critical isthmus of the reentrant circuit, as indicated by finding the site with a continuous activity spanning diastole or with an isolated mid-diastolic potential (see Fig. 5.8). One caveat is that focal tachycardias can occur in patients with scar, and the focus can be imbedded in scar tissue; in this setting, propagation from the source to a site at which enough atrium (or ventricle) is activated to generate a P (or QRS complex) can be significantly delayed, such that the timing of the earliest site may be considerably longer than 50 milliseconds.

Epicardial Versus Endocardial Mapping

Activation mapping is predominantly performed endocardially. Occasionally, epicardial mapping is required because of an inability to ablate

Fig. 5.6 Myocardial Activation Patterns of Simple and Fractionated Electrograms. *Top panels*, Homogeneous activation front across myocardial cells results in a simple electrogram. *Bottom panels*, Inhomogeneous activation front, in which the direction of the activation front changes, due to either the direction of propagation and coupling structure of myocardial fibers (anisotropy) or the functional or pathological barriers between myocardial fibers, will result in a complex electrogram with multiple deflections. (From van der Does LJME, de Groot NMS. Inhomogeneity and complexity in defining fractionated electrograms. *Heart Rhythm*. 2017;14:616–624.)

some VTs, ATs, or AV BTs by using the endocardial approach. Limited epicardial mapping can be performed with special recording catheters that can be steered in the branches of the CS. This technique has been used for mapping VTs and AV BTs, but its scope is limited by the anatomy of the coronary venous system.

A more common epicardial mapping technique utilizes the subxiphoid percutaneous approach for accessing the epicardial surface. This technique has become an important adjunctive strategy to ablate a diverse range of cardiac arrhythmias, especially in patients with scar-related VT, in whom more reentrant circuits with vulnerable isthmuses are on the epicardial surface. The same fundamental principles of activation mapping are used for both endocardial mapping and epicardial mapping.⁹

Mapping Catheters

The simplest form of mapping is achieved by moving the mapping catheter sequentially to sample various points of interest on the endocardium to measure local activation. The precision of locating the source of a particular electrical signal depends on the distance between the recording electrodes on the mapping catheter. For ablation procedures, recordings between adjacent electrode pairs are commonly used (e.g., between electrodes 1 and 2, 2 and 3, and 3 and 4), with 1- to 5-mm interelectrode spacing. In some studies, wider bipolar recordings (e.g.,

between electrodes 1 and 3 and 2 and 4) have been used to provide an overlapping field of view. For bipolar recordings, the signal of interest can be beneath the distal or the proximal electrode of the recording pair. As noted, this is germane in that ablation energy can be delivered only from the distal (tip) electrode (Fig. 5.9). Because of this, many operators display the unipolar recordings from each component of the distal bipole, in order to determine which electrode is actually recording the earliest activity.

Mapping Focal Tachycardias

The goal of activation mapping of focal-appearing tachycardias (automatic, triggered activity, or microreentrant) is identifying the site of origin, defined as the site with the earliest presystolic bipolar recording in which the distal electrode shows the earliest intrinsic deflection and QS unipolar electrogram configuration (Figs. 5.10 and 5.11). Local activation at the site of origin precedes the onset of the tachycardia complex on the surface ECG by an average of 10 to 40 milliseconds. Earlier electrograms occurring in mid-diastole, as in the setting of macroreentrant tachycardias, are not expected and do not constitute a target for mapping.¹

Endocardial activation mapping of focal tachycardias can trace the origin of activation to a specific area, from which it spreads centrifugally. There is generally an electrically silent period in the tachycardia cycle

Fig. 5.7 Use of Ventricular Extrastimulus (VES) to Clarify Onset of the P Wave During Atrial Tachycardia (AT). A single VES (S) delivered during AT advances the timing of ventricular activation to show the P wave (long arrow) by itself without the overlying ST segment and T wave, which made it difficult to determine P wave onset during ongoing tachycardia. The dashed line denotes onset of the P wave; timing of the reference electrogram (high right atrium [HRA]; short arrow) can thereafter be used as a surrogate for P wave onset. Abl_{dist}, Distal ablation; Abl_{prox}, proximal ablation; Abl_{uni}, unipolar ablation; RV, right ventricle.

Fig. 5.8 Focal Versus Macroreentrant Ventricular Tachycardia (VT). Top, Electrocardiogram (ECG) and intracardiac electrograms from the mapping (Map) and right ventricle (RV) catheters. Bottom, Depictions of events at sites where mapped electrograms are obtained. Left, VT focus fires and activation spreads to normal myocardium within 30 to 40 milliseconds, generating a QRS complex. Thus the electrogram at the site of the focus is generally 40 milliseconds or less prior to the QRS onset. Right, In contrast, in a macroreentrant VT, some myocardium is being activated at each instant in the cardiac cycle. During surface ECG diastole, only a few cells are activating (too few to cause surface ECG deflections). The area of a protected diastolic corridor, often cordoned off by scar, contains mid-diastolic recordings and is an attractive ablation site. The 0 isochrone indicates the time at which the QRS complex begins.

Fig. 5.9 Hypothetical Recordings Showing Complimentary Information From Unipolar and Bipolar Electrograms. A point source of activation is at the center of the concentric rings (that depict radial spread of activation from the source). (A) The ablation electrode (1) is directly over the source; its unipolar electrogram shows a QS configuration with a steep downstroke coincident with the moment of depolarization (*dashed line*). The bipolar electrogram (electrodes 1 and 2) is likewise early and the bipolar and unipolar recordings "agree." (B) The catheter has been moved such that electrode 2 is now directly over the point source. While bipolar recording 1-2 is the same as before (since 1 of its electrodes is over the source), now electrode 1 (the tip, through which ablation energy is delivered) is no longer as early in timing as 1-2 nor is there a QS configuration (both of which features are found in unipolar 2). Here, unipolar 1 and bipolar 1-2 "disagree."

length (TCL) that is reflected on the surface ECG by an isoelectric line between tachycardia complexes. Intracardiac mapping shows significant portions of the TCL without recorded electrical activity, even when recording from the entire cardiac chamber of tachycardia origin. However, in the presence of complex intramyocardial conduction disturbances, activation during focal tachycardias can extend over a large proportion of the TCL, and conduction spread can follow circular patterns suggestive of macroreentrant activation.¹⁰

Technique of activation mapping of focal tachycardias. Initially one should seek the general region of the origin of the tachycardia as indicated by the surface ECG. In the EP laboratory, additional data can be obtained by placing a limited number of catheters within the heart in addition to the mapping catheter or catheters; these catheters are frequently placed at the right ventricle (RV) apex, His bundle region, high RA, and CS. During initial arrhythmia evaluation, recording from this limited number of sites allows a rough estimation of the site of interest. Mapping simultaneously from as many sites as possible greatly enhances the precision, detail, and speed of identifying regions of interest.

Subsequently, a single mapping catheter is moved under fluoroscopic guidance over the endocardium of the chamber of interest to sample

bipolar signals. Using standard equipment, mapping a tachycardia requires recording and mapping performed at several sites, based on the ability of the investigator to recognize the mapping sites of interest from the morphology of the tachycardia on the surface ECG and baseline intracardiac recordings.

Local activation time is then determined from the filtered (30 to 300 Hz) bipolar signal recorded from the distal electrode pair on the mapping catheter; this time is determined and compared with the timing reference (fiducial point). Activation times are generally measured from the onset of the first rapid deflection of the bipolar electrogram to the onset of the tachycardia complex on the surface ECG or surrogate marker (see Fig. 5.7). Using the onset (rather than the peak or nadir) of a local bipolar electrogram is often preferable because it is easier to determine reproducibly, especially when measuring heavily fractionated, low-amplitude local electrograms.

Once an area of relatively early local activation is found, small movements of the catheter tip in the general target region are undertaken until the site is identified with the earliest possible local activation relative to the tachycardia complex. Recording from multiple bipolar pairs from a multipolar electrode catheter is helpful in that if the proximal

Fig. 5.10 Focal Atrial Tachycardia. The unipolar electrogram recorded by the distal ablation electrode (Abl_{uni}) shows a QS configuration, and its timing coincides with the distal ablation (Abl_{dist}) recording at the site of successful ablation. The dashed line marks the onset of the P wave on the surface electrocardiogram. Abl_{prox} , proximal ablation; CS_{dist} , distal coronary sinus; CS_{prox} , proximal coronary sinus; His_{dist} , distal His bundle; His_{mid} , middle His bundle; His_{prox} , proximal His bundle; HRA , high right atrium.

Fig. 5.11 Sinus Rhythm and a Single Premature Ventricular Complex From a Patient With Focal Ventricular Tachycardia. The unipolar ablation site (Abl_{uni}) show a QS configuration, the most rapid slope of which times with the initial peak in the distal ablation (Abl_{dist}) recording (arrows) at the site of successful ablation. The dashed line marks the onset of the QRS complex on the surface electrocardiogram. Abl_{prox} , proximal ablation; HRA , high right atrium; RV , right ventricle.

pair has a more attractive electrogram than the distal, the catheter may be withdrawn slightly to achieve the same position with the distal electrode.

Once the site with the earliest bipolar signal is identified, the unipolar signal from the distal ablation electrode should be used to supplement bipolar mapping. The unfiltered (0.05 to 300 Hz) unipolar signal morphology should show a monophasic QS complex with a rapid negative deflection if the site was at the origin of impulse formation (see Figs. 5.10 and 5.11). However, the size of the area from which a QS complex can be larger than the tachycardia focus, exceeding 1 cm in diameter. Thus a QS complex should not be the only mapping finding used to guide ablation. Successful ablation is unusual, however, at sites with an RS complex on the unipolar recording because these are generally distant from the focus (see Fig. 5.2). Concordance of the timing of the onset of the bipolar electrogram with that of the filtered or unfiltered unipolar electrogram (with the rapid downslope of the S wave of the unipolar QS complex coinciding with the initial peak of the bipolar signal) helps ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrogram. A tissue contact force measuring 10 to 20 g, as well as the presence of slight ST elevation on the unipolar recording and the ability to capture the site with unipolar pacing, are used to indicate good electrode-tissue contact.⁶

Furthermore, a negative concordance of the vector of the initial (first 20 milliseconds) forces of both unipolar and bipolar electrograms (both being negative deflections), in conjunction with electrogram temporal relationship assessment, further improves the accuracy of conventional mapping to localize the site of origin of PVCs (Fig. 5.12). In a recent report, the presence of this criterion ("negative concordance") at sites fulfilling other conventional criteria used to guide focal PVC ablation highly predicted the acute success rate of radiofrequency ablation with a sensitivity and specificity of 94% and 95%, respectively. Furthermore, its positive predictive value was significantly superior to those of all other conventional criteria (76% vs. 33% to 43%).⁶

Mapping Macroreentrant Tachycardias

The main goal of activation mapping of macroreentrant tachycardias (e.g., post-MI VT, macroreentrant AT) is identification of the isthmus critical for maintenance of the macroreentrant circuit. The site of origin of a tachycardia is the source of electrical activity producing the tachycardia complex; although this is a discrete site of impulse formation in focal rhythms, during macroreentry it can represent the exit site from the diastolic pathway (i.e., from the critical isthmus of the reentrant circuit) to the myocardium that gives rise to the ECG deflection. During macroreentry, an isthmus is defined as a corridor of conductive myocardial tissue bounded by nonconductive tissue (barriers) through which the depolarization wavefront must propagate to perpetuate the tachycardia. These barriers can be scar areas or naturally occurring anatomical or functional (present only during tachycardia, but not in sinus rhythm) obstacles. The earliest presystolic electrogram closest to mid-diastole is the most commonly used definition for the site of origin of the reentrant circuit. However, recording continuous diastolic activity or bridging of diastole at adjacent sites, or mapping a discrete diastolic pathway, is more specific. Therefore the goal of activation mapping during macroreentry is finding the site, or sites, with continuous electrical activity spanning diastole or with an isolated mid-diastolic potential; once such a site has been located, further testing should be done to ensure that the tissue generating that electrogram is in fact integral to the tachycardia rather than a bystander. Unlike focal tachycardias, a presystolic electrogram preceding the tachycardia complex by 10 to 40 milliseconds is not adequate in defining the site of origin of a macroreentrant tachycardia (see Figs. 5.8, 5.13, and 5.14).¹¹

Fig. 5.12 Negative Concordance in the Initial Forces of Unipolar and Bipolar Electrograms. Surface electrocardiogram and intracardiac recordings during spontaneous (A and B) and mechanical (C) premature ventricular contractions (PVCs) in the same patient. The bottom diagrams show the presumed corresponding positions of the ablation catheter relative to the site of origin (*star*). An initially positive bipolar electrogram is recorded at the unsuccessful ablation site (A) where the catheter tip is not precisely at the site of origin (the *bottom left* diagram). A negative concordance in the initial (first 20 milliseconds) forces of both bipolar and unipolar recordings is observed at the successful ablation site (B) and during mechanical PVCs (C) where the catheter tip is touching the site of origin (the *bottom right* diagram). Note that in all cases there is a QS pattern in the unipolar electrogram and a discrete prematurity relative to the QRS onset (*dotted vertical lines*). The mechanical PVC (C) has a different QRS morphology as compared with the spontaneous PVCs (A and B). ABL, Ablation catheter; D and P, bipolar recordings from the distal (1-2) and proximal (3-4) electrode pairs, respectively; UNI1 and UNI2, unipolar recordings from the distal (1) and proximal (2) electrodes of the ablation catheter, respectively. (From Sorgente A, Epicoco G, Ali H, et al. Negative concordance pattern in bipolar and unipolar recordings: an additional mapping criterion to localize the site of origin of focal ventricular arrhythmias. *Heart Rhythm*. 2016;13:519–526.)

However, identification of critical isthmuses is often challenging. The abnormal area of scarring, where the isthmus is located, is frequently large and contains side branch pathways (bystanders) that confound mapping. In addition, multiple potential reentry circuits can be present, giving rise to multiple different tachycardias in a single patient. Furthermore, in abnormal regions such as infarct scars, the tissue beneath the recording electrode can be small relative to the surrounding myocardium outside the scar; thus a large far-field signal can obscure the small local potential. For this reason, bipolar recordings are preferred in scar-related VTs because the noise is removed and high-frequency components are more accurately seen. Unipolar recordings are usually of little help when mapping arrhythmias associated with regions of

scar, unless the recordings are filtered to remove far-field signal; even so, signal amplitude in the unipolar recording is often extremely small and may be difficult to distinguish from noise. Much of the far-field signal in a unipolar recording consists of lower frequencies than the signal generated by local depolarization because the high-frequency content of a signal diminishes more rapidly with distance from the source than the low-frequency content. Therefore high-pass filtering of unipolar signals (at 30 or 100 Hz) is generally used when mapping scar-related arrhythmias to reduce the far-field signal and improve detection of lower amplitude local signals from abnormal regions.

Although activation mapping alone is usually inadequate for defining the critical isthmus of a macroreentrant tachycardia, it can help

Fig. 5.13 Macroeentrant Atrial Tachycardia. Electrical activity spans the tachycardia cycle length (*shaded*); thus a merely presystolic electrogram is a poor indicator of optimal ablation site. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium.

Fig. 5.14 Macroeentrant Post-Myocardial Infarction Ventricular Tachycardia. Electrical activity spans diastole and nearly the tachycardia cycle length (*shaded*); thus a simply presystolic electrogram is a poor indicator of the optimal ablation site. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *HRA*, high right atrium; *RV*, right ventricle.

guide other mapping modalities (e.g., entrainment or pace mapping, or both) to the approximate region of the isthmus.

Continuous electrical activity. Theoretically, if reentry were the mechanism of the tachycardia, electrical activity should occur throughout the tachycardia cycle. For example, in macroreentrant AT, the recorded electrical activity at different locations in the atrium should span the TCL (see Fig. 5.13).¹²

For macroreentrant VT, conduction during diastole is extremely slow and is in a small area so that it is not recorded on the surface ECG. The QRS complex is caused by propagation of the wavefront from the exit of the circuit from that isthmus to the surrounding myocardium. After leaving the exit of the isthmus, the circulating wavefront propagates through a broad path (loop) along the border of the scar, back to the

Fig. 5.15 Mid-Diastolic Potential During Ventricular Tachycardia (VT). Duration of diastole (*shaded area*), with isolated mid-diastolic potential from the site at which ablation eliminated VT (*arrows*). *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *Abl_{uni}*, unipolar ablation; *HRA*, high right atrium; *RVA*, right ventricular apex.

entrance of the isthmus (see Fig. 5.8). Continuous diastolic activity is likely to be recorded only if the bipolar pair records from a small circuit; if a large circuit is present (i.e., the reentrant circuit is larger than the recording area of the catheter, or the catheter is not covering the entire circuit), non-holodiastolic activity will be recorded. In such circuits, repositioning of the catheter to other sites may allow visualization of what is termed *bridging of diastole*; electrical activity in these adjacent sites spans diastole.

All areas from which diastolic activity is recorded are not necessarily part of the reentrant circuit. Such sites can reflect late activation of sites that may not be related to the tachycardia circuit. Analysis of the response of these electrograms to spontaneous or induced changes in TCL is critical in deciding their relationship to the tachycardia mechanism. In addition, electrical signals that come and go throughout diastole should not be considered continuous (eFig. 5.2). For continuous activity to be consistent with reentry, it must be demonstrated that such electrical activity is required for initiation and maintenance of the tachycardia, so that termination of the continuous activity, either spontaneously or following stimulation, without affecting the tachycardia, would exclude such continuous activity as requisite for sustaining the tachycardia. It is also important to verify that an electrogram that extends throughout diastole is not just a broad electrogram whose duration equals the TCL. This can be achieved by analyzing the local electrogram during pacing at a pacing cycle length (PCL) comparable to TCL; if pacing produces continuous diastolic activity in the absence of tachycardia, the continuous electrogram may have no mechanistic significance. Furthermore, the continuous activity should be recorded from a circumscribed area, and motion artifact should be excluded.

Mid-diastolic activity. An isolated mid-diastolic potential is defined as a low-amplitude, high-frequency diastolic potential separated from the preceding and subsequent electrograms by an isoelectric segment (Fig. 5.15). Sometimes these discrete potentials provide information that defines a diastolic pathway, which is believed to be generated from a narrow isthmus of conduction critical to the reentrant circuit. Localization of this pathway is critical for guiding catheter-based ablation.

Detailed mapping usually reveals more than one site of presystolic activity, and mid-diastolic potentials can be recorded from bystander sites attached to the isthmus. Therefore, regardless of where in diastole the presystolic electrogram occurs (early, middle, or late), its timing and appearance on initiation of the tachycardia, although necessary, does not confirm its relevance to the tachycardia mechanism. One must always confirm that the electrogram is required to maintain, and cannot be dissociated from, the tachycardia. Thus, during spontaneous changes

eFig. 5.2 Diastolic Recordings During Ventricular Tachycardia (VT). Note that the diastolic electrograms (arrows) during VT have a 2:1 conduction ratio. Cells causing these recordings are clearly not integrally involved in the ongoing arrhythmia. They are not atrial because atrial ventricular dissociation is evident in the high right atrium (HRA) recording. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *RVA*, right ventricular apex.

in the TCL or those produced by programmed stimulation, the electrogram, regardless of its timing in diastole, should show a fixed relationship with the subsequent tachycardia complex (and not the preceding one). Very early diastolic potentials (in the first half of diastole) can represent an area of slow conduction at the entrance of a protected isthmus. These potentials remain fixed to the prior tachycardia complex (exit site from the isthmus), and a delay between this complex and the subsequent tachycardia complex would reflect a delay in entering or propagating through the protected diastolic pathway. Although such potentials that are related to the prior QRS complex can in fact be integral to the tachycardia (e.g., if the variability in cycle length [CL] is due to varying delay in the diastolic corridor “downstream” from the recording site), this is not guaranteed as it is when the electrogram is tightly related to the subsequent QRS complex.

If after very detailed mapping the earliest recorded site is not at least 50 milliseconds presystolic, this suggests that the map is inadequate (most common), the mechanism of tachycardia is not macroreentry, or the diastolic corridor is deeper than the subendocardium (in the midmyocardium or subepicardium).

Limitations

Standard catheter endocardial mapping, as performed in the EP laboratory, is limited by the number, size, and type of electrodes that can be placed within the heart. Therefore these methods do not simultaneously cover a vast area of the endocardial surface. Time-consuming, point-by-point maneuvering of the catheter is required to trace the origin of an arrhythmic event and its activation sequence in the neighboring areas.

The success of roving point mapping depends on the sequential beat-by-beat stability of the activation sequence being mapped and the ability of the patient to tolerate sustained arrhythmia. Therefore it can be difficult to perform activation mapping in poorly inducible tachycardias, in hemodynamically unstable tachycardias, and in tachycardias with unstable morphology. Sometimes poorly tolerated rapid tachycardias can be slowed by antiarrhythmic agents to allow for mapping. Alternatively, mapping can be facilitated by starting and stopping the tachycardia after data acquisition at each site. In addition, newer techniques (e.g., basket catheter, electroanatomic mapping, and noncontact mapping) can facilitate activation mapping in these cases by simultaneous multipoint mapping.

Although activation mapping is adequate for defining the site of origin of focal tachycardias, it is insufficient by itself in defining the critical isthmus of macroreentrant tachycardias, and adjunctive mapping modalities (e.g., entrainment mapping, pace mapping) are required. Moreover, the laborious process of precise mapping with conventional techniques can expose the electrophysiologist, staff, and patient to undesirable levels of radiation from the extended fluoroscopy time.

Using conventional activation mapping techniques, it is difficult to conceive the three-dimensional orientation of cardiac structures because a limited number of recording electrodes guided by fluoroscopy is used. Although catheters using multiple electrodes to acquire data points are available, the exact location of an acquired unit of EP data is difficult to ascertain because of inaccurate delineation of the location of anatomical structures. The inability to accurately associate the intracardiac electrogram with a specific endocardial site accurately also limits the reliability with which the roving catheter tip can be placed at a site that was previously mapped. This results in limitations when the creation of long linear ablation lesions is required to modify the substrate, as well as when multiple isthmuses or channels are present. The inability to identify, for example, the site of a previous ablation increases the risk of repeated ablation of areas already dealt with and the likelihood that new sites can be missed.

ENTRAINMENT MAPPING

Fundamental Concepts

To help understand the concept of entrainment, a hypothetical reentrant circuit is shown in Fig. 5.16. This reentrant circuit has several components—a common pathway, an exit site, an outer loop, an inner loop, an entry site, and bystander sites.

- The reentrant wavefront propagates through the common central pathway (protected critical isthmus) during electrical diastole. Because this zone of slow conduction is usually composed of a small amount of myocardium and is bordered by anatomical or functional barriers preventing the spread of the electrical signal except in the orthodromic direction, propagation of the wavefront in the protected isthmus is electrocardiographically silent.
- The exit site is the site at which the reentrant wavefront exits the protected isthmus to start activation of the rest of the myocardium, including the outer loop. Activation of the exit site corresponds to the onset of the tachycardia complex on the surface ECG.
- The entrance is where the reentrant wavefront enters the critical isthmus.
- The outer loop is a pathway outside the scars connecting to the common central pathway and forming a circuit, and at the same time communicating with the main body of myocardium. The reentrant wavefront propagates through the outer loop while at the same time activating the rest of the myocardium. Activation of the outer loop corresponds to electrical systole (P wave during AT and QRS during VT) on the surface ECG.
- An inner loop is a conduction pathway within scars, communicating with the common central pathway forming a circuit. The inner loop can serve as an integral part of the reentrant circuit or function as a bystander pathway; the timing of activation, like the outer loop, is typically during electrical systole.
- The dominant loop is the circuit loop outside the common central pathway with the shortest conduction time. If conduction through the inner loop is slower than conduction from the exit to entrance sites (through the outer loop), the inner loop will serve as a bystander, and the outer loop will be the dominant loop. If conduction through the inner loop is faster than conduction through the outer loop, it will form an integral component of the reentrant circuit and is designated the dominant inner loop; ablation of the inner loop in this case may cause an abrupt change in TCL without change in QRS because the inner loop is no longer operative and the outer loop now becomes the default pathway.
- Bystander sites are sites that are activated by the reentrant wavefront but are not an essential part of the reentrant circuit. These sites can be remote, adjacent, or attached to the circuit. An attached bystander site represents a dead-end pathway (or a blind pouch) that communicates with the common central pathway or any inner loop and has no other exits.¹³

Understanding the concepts associated with resetting is critical to understanding entrainment. When a premature stimulus is delivered to sites remote from the reentrant circuit, it can interact with the circuit in different ways. When the stimulus is late-coupled, it may reach the circuit after it has just been activated by the reentrant wavefront. Consequently, although the extrastimulus may have resulted in activation of part of the myocardium, it fails to affect the reentrant circuit, and the reentrant wavefront continues to propagate in the critical isthmus and through the exit site to produce the next tachycardia complex on time. Fusion can be observed, but not resetting.

To reset a reentrant tachycardia, the paced wavefront must reach the reentrant circuit (entry site), encounter excitable tissue within the circuit (i.e., enter the excitable gap of the reentrant circuit), collide in

Site	Electrogram Timing in VT	Entrainment with Concealed Fusion	Entrained [S-QRS] – [Egm-QRS]	[S-QRS] TCL	PPI – TCL	Sinus Rhythm Pacemap QRS vs. VT

Fig. 5.16 Representation of a Ventricular Tachycardia (VT) Circuit. The illustration shows a common diastolic pathway, entrance and exit sites, inner and outer loops, adjacent bystander dead-end paths in three locations, and remote bystander sites. The accompanying table describes the behavior of each of these locations during VT, as well as pacing during VT and sinus rhythm. Egm, Electrogram; S, stimulus; PPI, post pacing interval; TCL, tachycardia cycle length.

the antidromic (retrograde) direction with the previous tachycardia complex, and propagate in the orthodromic (anterograde) direction through the same tachycardia reentrant path (critical isthmus) to exit at an earlier than expected time and perpetuate the tachycardia (Fig. 5.17). If the extrastimulus encounters fully excitable tissue, as commonly occurs in reentrant tachycardias with large excitable gaps, the tachycardia is advanced by the extent that the paced wavefront arrives

at the entrance site prematurely. If the tissue is partially excitable, as can occur in reentrant tachycardias with small or partially excitable gaps, or even in circuits with large excitable gaps when the extrastimulus is very premature, the paced wavefront will encounter some conduction delay in the orthodromic direction within the circuit. Consequently, the degree of advancement of the next tachycardia complex depends on both the degree of prematurity of the extrastimulus and

Fig. 5.17 Entrainment of Ventricular Tachycardia (VT). (A) Pure VT is shown in yellow (*right bundle branch block, right axis*), pure right ventricle (RV) pacing in red (*left bundle branch block, left axis*). A mid-diastolic potential during VT (*arrow*) is recorded by the mapping catheter. (B) Pacing the RV at 460 milliseconds (30 milliseconds faster than VT), each paced complex is a stable blend of pacing and VT (*gold*). This illustrates fixed fusion. After cessation of pacing, VT resumes. (C) Pacing the RV faster (430 milliseconds), all complexes are again identical to each other but different than with pacing at 460 milliseconds; they look slightly more like pure RV pacing (*deeper gold shading*). (D) Pacing the RV faster still (400 milliseconds), QRS complexes again are identical to each other (fixed fusion) but look progressively more like fully paced (progressive fusion). (E) Finally, with pacing rapidly enough, an antidromic wavefront captures the diastolic potential, QRS complexes become fully paced, and when pacing ceases, sinus rhythm resumes. This figure demonstrates all established entrainment criteria (fixed fusion at a given paced cycle length [CL], progressive fusion over a range of paced CLs, and antidromic capture of critical circuit elements leading to termination of the tachycardia).

the degree of slowing of its conduction within the circuit. Therefore the reset tachycardia complex may be early, on time, or later than expected.^{13,14}

Termination of the tachycardia occurs when the extrastimulus collides with the preceding tachycardia impulse antidromically and blocks in the reentrant circuit orthodromically. This occurs when the premature

impulse enters the reentrant circuit early enough in the relative refractory period because it fails to propagate in the anterograde direction, given that it encounters absolutely refractory tissue (see Fig. 5.17). In the retrograde direction, it encounters increasingly recovered tissue and is able to propagate until it meets the incoming circulating wavefront and terminates the arrhythmia.

Entrainment is the continuous resetting of a reentrant circuit by a train of capturing stimuli. However, following the first stimulus of the pacing train that penetrates and resets the reentrant circuit, the subsequent stimuli interact with the “reset circuit,” which has an abbreviated excitable gap. The first entrained complex results in retrograde collision between the stimulated and the tachycardia wavefronts, whereas in all subsequent beats, the collision occurs between the currently stimulated wavefront and that stimulated previously. Depending on the degree that the excitable gap is preexcited (shortened) by the first resetting stimulus, subsequent stimuli can fall on fully or partially excitable tissue. Entrainment is said to be present when two consecutive extrastimuli conduct orthodromically through the circuit with the same conduction time while colliding antidromically with the preceding paced wavefront.¹³

During entrainment, each pacing impulse creates two activation wavefronts—one in the orthodromic direction and the other in the antidromic direction. The wavefront in the antidromic direction collides with the existing tachycardia wavefront. The wavefront that enters the reentrant circuit in the orthodromic direction (i.e., the same direction as the spontaneous tachycardia wavefront) conducts through the critical isthmus, resets the tachycardia, and emerges through the exit site to activate the myocardium and collide with the antidromically paced wavefront from the next paced stimulus. This sequence continues until cessation of pacing or development of block somewhere within the reentrant circuit. Because all pacing impulses enter the tachycardia circuit during the excitable gap, each paced wavefront advances and resets the tachycardia. Thus when pacing is terminated, the last paced impulse continues to activate the entire tachycardia reentrant circuit orthodromically at the PCL and also activates the entire myocardium orthodromically on exiting the reentrant circuit (as this time there is no paced antidromic wavefront with which to collide).¹⁴

Entrainment does not require that the pacing site be located in the reentrant circuit. The closer the pacing site is to the circuit, however, the less premature a single stimulus needs to be to reach the circuit and, with pacing trains, the fewer stimuli will be required before a stimulated wavefront reaches the reentrant circuit without being extinguished by collision with a wave emerging from the circuit. Overdrive pacing at relatively long PCLs (i.e., 10 to 30 milliseconds shorter than the TCL) can almost always entrain reentrant tachycardias. However, the number of pacing stimuli required to entrain the reentrant circuit depends on the TCL, the duration of the excitable gap of the tachycardia, refractoriness at the pacing site, and the conduction time from the stimulation site to the reentrant circuit.¹⁵

Entrainment Criteria

During constant-rate pacing, entrainment of a reentrant tachycardia results in the activation of all myocardial tissue responsible for maintaining the tachycardia at the PCL, with the resumption of the same tachycardia morphology following cessation of pacing and the first postpacing ECG tachycardia complex displaying no fusion but occurring at a return cycle equal to the PCL. Unfortunately, it is almost impossible to document the acceleration of all the tissue responsible for maintaining the reentrant circuit to the PCL. Importantly, the mere acceleration of the tachycardia to the pacing rate and the subsequent resumption of the original tachycardia after the cessation of pacing do not establish the presence of entrainment; these can be seen with any type of tachycardia, including focal automatic tachycardias. Therefore several surface ECG and intracardiac electrogram criteria have been proposed for establishing the presence of entrainment (see Fig. 5.17; Box 5.1), largely dealing with the phenomenon of fusion during pacing.¹⁶

Demonstration of one or more of the four criteria proves the presence of entrainment and supports a reentrant mechanism, but their absence does not exclude entrainment or reentry. Pacing at different

BOX 5.1 Criteria for Entrainment

1. Constant fusion during overdrive pacing at a given cycle length, except for the last captured P wave which is entrained but not fused.
2. Progressive fusion during overdrive pacing from the same site at different cycle lengths.
3. When overdrive pacing at a constant rate during tachycardia results in tachycardia termination, there is the demonstration of localized conduction block to a site (or sites) for one paced beat associated with interruption of the tachycardia, followed by activation of that site (or sites) by the next paced P wave from a different direction and with a shorter conduction time.
4. During overdrive pacing at two different rates during tachycardia, there is change in conduction time to and electrogram morphology at the electrode recording site.

endocardial sites and at multiple PCLs and recording activation sequence from multiple intracardiac locations (especially in the setting of macroreentrant AT) is often required to demonstrate one or more of the entrainment criteria and hence establish the diagnosis of macroreentrant tachycardia.¹⁷

Of note, the third “entrainment criterion” seems to be a paradox, since it is based on tachycardia termination by overdrive pacing, invalidating the presence of “entrainment” which, by definition, requires “resumption of the same tachycardia morphology following cessation of pacing.” Nevertheless, this criterion demonstrates that the mechanism of tachycardia termination is related to block of an orthodromic wavefront after it has entered the circuit. When localized block to a recording site occurs and the same site is activated in subsequent beats with a shorter conduction time, it means that such a site had been originally activated orthodromically.¹³

Fusion During Entrainment

A stimulated impulse is said to be fused when its morphology is a hybrid between that of a fully paced complex morphology (when pacing is performed at identical site and rate but in the absence of tachycardia) and a tachycardia complex morphology (in the absence of pacing). Fusion can be observed on the surface ECG, intracardiac recordings, or both. For fusion to be observed on the surface ECG, the tachycardia and stimulated wavefronts must collide within the reentrant circuit after the tachycardia wavefront has exited from the isthmus. This requires the paced wavefront to have access to an entrance site of the reentrant circuit that is anatomically distinct from the exit site. If the antidromically stimulated wavefront penetrates the reentrant circuit and collides with the tachycardia wavefront (or the previously stimulated orthodromic wavefront) before the point at which the tachycardia wavefront would be exiting to the mass of the myocardium, then no fusion will be evident on the surface ECG, and the surface ECG will appear entirely paced (Fig. 5.18).^{13,18}

The ability to demonstrate surface ECG fusion requires that a significant mass of myocardium be depolarized by both the extrastimulus and the tachycardia. The degree of fusion represents the relative amount of myocardium depolarized by the two separate wavefronts. The relative degree of myocardium antidromically activated by the paced wavefront depends on the site of pacing relative to the reentrant circuit, the PCL, and the degree of conduction delay within the reentrant circuit. With a single extrastimulus, the farther the stimulation site is from the reentrant circuit, the less likely ECG fusion will be to occur, because the extrastimulus must be delivered at a shorter coupling interval (well before the tachycardia wavefront exits the circuit) in order to reach the circuit with adequate prematurity. Therefore, by the time the tachycardia

Fig. 5.19 QRS Fusion During Entrainment of Ventricular Tachycardia (VT). Progressive electrocardiogram fusion is shown over a range of paced cycle lengths (CLs). Pure tachycardia complexes are shown on the left; fully paced complexes are shown on the right. As the paced CL shortens, complexes gradually appear more like those that are fully paced. RV, Right ventricle; RVA, right ventricular apex.

fusion and more fully paced morphology. Such phenomena (referred to as “variable fusion”) should be distinguished from “constant fusion” and “progressive fusion” characteristic of entrainment, and sometimes this distinction requires pacing for long intervals to demonstrate variable degrees of fusion. Moreover, overdrive pacing frequently results in suppression (automatic) or acceleration (triggered activity) of focal tachycardias, rather than resumption of the original tachycardia with an unchanged TCL.^{13,17}

During entrainment, varying degrees of fusion at different pacing rates are caused by a progressive increase in the amount of myocardium activated by the antidromic wavefront at progressively shorter PCLs; although fusion remains fixed at each of the PCLs, a different degree of fixed fusion is manifest at different PCLs (see Figs. 5.17 and 5.19). At slower PCLs, a larger amount of the myocardium is activated by the orthodromic wavefront exiting from the reentrant circuit prior to its intracardiac collision, with the subsequent antidromic wavefront incoming from the pacing site. With a faster pacing rate, more myocardium is antidromically activated because the orthodromic wavefront must continue to traverse the zone of slow conduction within the reentrant circuit, thus creating progressive fusion with changing PCLs. In the extreme situation, the antidromic wavefront can capture the exit site of the reentrant circuit (i.e., capture of the presystolic electrogram during tachycardia) and produce a fully paced complex on the surface ECG. Once this occurs, pacing at shorter PCLs does not cause further progressive fusion, although entrainment is still present. As noted, progressive fusion at decreasing PCLs during entrainment of tachycardia excludes the possibility of automaticity or triggered activity as the mechanism of the tachycardia. In those cases, overdrive pacing would yield solely the morphology of the pacing stimulus for a nonprotected focus or would yield varying (not progressive) degrees of fusion for a

protected focus with entrance block. Of note, a microreentrant circuit with entrance block could also yield variable fusion during overdrive pacing; thus this finding would not exclude reentry as the underlying mechanism.¹³

The traditional definition of entrainment states that following cessation of pacing, the same tachycardia morphology resumes, with the first postpacing ECG tachycardia complex displaying no fusion but occurring at a *return cycle equal to the PCL*. On cessation of pacing, the last paced wavefront traverses the protected isthmus and exits the circuit to produce a normal (nonfused) tachycardia ECG complex because there is no paced antidromic wavefront with which to fuse. The wavefront continues around the reentrant circuit to maintain the tachycardia. However, demonstration of the first return cycle (measured at the onset of the ECG complex) that is equal to the PCL is difficult. This response is rare and occurs only when the pacing stimulus occurs after the onset of the tachycardia ECG complex (P wave or QRS), whereby the initial part of the fused complex is activated by the orthodromic wavefront exiting the tachycardia circuit. Then, the first nonpaced complex will occur at the PCL because it will really be orthodromically activated by the last paced beat. More commonly, constant fusion of the surface ECG occurs without the first nonpaced beat occurring at the PCL. When surface ECG fusion occurs, the initial portion of the ECG complex usually reflects activation of the myocardium by the paced wavefront, whereas the terminal portion represents the orthodromically activated wavefront exiting from the tachycardia circuit. The point at which this wavefront exits the circuit can be late in the surface ECG complex. The degree to which the first ECG complex postpacing interval (PPI) exceeds the PCL is primarily a reflection of the time from the onset of the paced surface ECG complex to the exit of the orthodromic wavefront from the reentrant circuit. This represents the period of time during which

the myocardium is depolarized by the stimulated wavefront before the activation of any portion of the myocardium by the wavefront exiting the tachycardia circuit. Therefore, constant fusion occurring in the absence of the first ECG PPI being equal to the PCL can be a valid manifestation of entrainment. In this situation, appropriate placement of intracardiac electrodes demonstrates orthodromic entrainment of some intracardiac recording sites occurring at the PCL, even though the last entrained ECG complex occurred at an interval longer than the PCL.¹³

Entrainment with manifest fusion. Entrainment with manifest fusion demonstrates surface ECG evidence of constant fusion at a constant pacing rate and progressive fusion with incremental-rate pacing (see Fig. 5.19). When entrainment is manifest, the last captured wave is entrained at the PCL but does not demonstrate fusion.¹³

Demonstration of the presence of manifest fusion during entrainment requires knowledge of the tachycardia surface ECG complex morphology as well as that of pure pacing (at the same site and rate) in the absence of tachycardia. However, in the setting of macroreentrant AT, P wave morphology during tachycardia or pure pacing may not be easily visualized in the presence of overlapping ST-T waves; hence intraatrial activation sequence can be utilized as a surrogate to ECG morphology to demonstrate fusion. Manifest fusion is said to be present when the ECG morphology (or intracardiac activation sequence) is a hybrid of the tachycardia complex morphology and that observed during pure pacing (see Figs. 5.17 and 5.19).

Sometimes fusion is difficult to recognize in the surface ECG because the morphology of the purely paced ECG complex may not be readily available. This can occur, for example, in patients presenting with persistent macroreentrant tachycardia, whereby pacing during NSR is not feasible. In this setting, the presence of manifest fusion can be inferred by one of the following observations:

1. The surface ECG complex (QRS/P wave) during entrainment is different from pure tachycardia morphology, and the onset of the QRS/P wave precedes the pacing stimulus artifact of each paced beat by a fixed interval (see Figs. 12.12 and 13.7). This observation provides evidence that the tachycardia wavefront has exited from the circuit, and that the initial portion of the QRS/P wave (inscribed before the pacing stimulus artifact) is activated orthodromically by the tachycardia wavefront while the latter portion is activated by the paced wavefront.
2. The surface ECG complex morphology (or intracardiac activation sequence) is different from the pure tachycardia morphology but is inconsistent with the expected morphology during pure pacing at a particular site (e.g., VT entrainment from the ventricular inferior wall producing QRS vector that is positive in inferior leads, or AT entrainment from the distal CS producing a proximal-to-distal CS activation sequence).
3. The demonstration of shortening of conduction time to (and change in electrogram morphology at) an intracardiac electrode recording site in response to increasing pacing rates during entrainment. Since *conduction velocity* with increasing rate is expected to either stay the same or decrease, but not increase, a decrease in *conduction time* (same paced site, same recorded site) in relation to faster pacing rate demonstrates that there are two routes of activation and that the faster one can only conduct to the recording site at faster pacing rates. This represents the fourth entrainment criterion and is the intracardiac equivalent of the second entrainment criterion (progressive fusion). The amount of tissue antidromically captured is critically dependent on the pacing rate. If the recording site is located in an area activated orthodromically at a slower rate and antidromically at a faster rate, the conduction time will dramatically shorten at the faster pacing rate.¹⁴

Entrainment with concealed fusion. Entrainment with concealed fusion (sometimes also referred to as “concealed entrainment” or “exact entrainment”) is defined as entrainment with orthodromic capture and a surface ECG complex (and intracardiac activation sequence) identical to that of the tachycardia (see Figs. 12.12 and 13.7).¹³

Entrainment with concealed fusion suggests that the pacing site is within a protected isthmus, either inside the reentrant circuit or outside the circuit but attached to its diastolic pathway (see Fig. 5.16). It is important to recognize that entrainment with concealed fusion can occur by pacing not only from the critical isthmus of the reentrant circuit, but also from bystander pathways, such as a blind alley, alternate pathway, or nondominant inner loop, that are attached to the protected isthmus that forms the diastolic pathway of the circuit but are not critical to the maintenance of reentry.

Pacing in a protected isthmus, either inside or outside (but attached to) the reentrant circuit isthmus, forces the paced wavefront to travel in one (orthodromic) direction through the same reentrant pathway as the tachycardia wavefront. Propagation of the paced wavefront in the opposite (antidromic) direction is prevented by either a dead-end (when one end of the protected pathway being paced is attached to the circuit and the other end is a dead end) or by colliding with the previous reentrant wavefront propagating orthodromically through the reentrant circuit (when both ends of the protected isthmus are attached to the circuit’s diastolic pathway, whether the isthmus is critical to the circuit or just a bystander). In either situation, the paced wavefront is forced to utilize the same reentry circuit exit to stimulate the rest of the myocardium and is prevented from stimulating the myocardium by propagating in any other direction. Hence the entrained ECG morphology is identical to that of the tachycardia.^{13,19}

Since only tissue near the pacing site within the critical isthmus is antidromically activated, evidence of fusion may be lacking. Compared with the intrinsic tachycardia, this antidromic capture may result in earlier intracardiac recordings from sites located adjacent to the pacing region. The morphological appearance of the ECG, however, is the same during entrainment as during the tachycardia.¹⁴

Entrainment with inapparent fusion. Entrainment with inapparent fusion (also referred to as “local” or “intracardiac” fusion) is said to be present when a fully paced morphology (with no ECG fusion) results, even when the tachycardia impulse exits the reentrant circuit (i.e., orthodromic activation of the presystolic electrogram is present). Fusion is limited to a small area and does not produce surface ECG fusion, and only intracardiac (local) fusion is recognized (Fig. 5.20; see Fig. 13.7).

Local fusion can occur only when the presystolic electrogram is activated orthodromically by the tachycardia wavefront. Collision with the last paced impulse must occur distal to the presystolic electrogram, either at the exit from the circuit or outside the circuit. In such cases, the return cycle measured at this local electrogram equals the PCL. Therefore a stimulus delivered after the onset of the tachycardia complex on the surface ECG during entrainment always demonstrates local fusion. This is to be distinguished from entrainment with antidromic capture. As noted, when antidromic (retrograde) capture of the local presystolic electrogram occurs, the return cycle, even when measured at the site of the presystolic electrogram, exceeds the PCL.

Entrainment with antidromic capture. During entrainment with a PCL pacing that is significantly shorter than the TCL, the paced impulse can penetrate the circuit antidromically and retrogradely capture the presystolic electrogram (exit site of the reentry circuit). In other words, the paced wavefront collides with the tachycardia wavefront within the diastolic pathway (protected isthmus) of the circuit. As a result, tachycardia wavefront cannot exit from the reentrant circuit and thus cannot contribute to myocardial activation. Therefore the ECG morphology

Fig. 5.20 Inapparent Fusion. The last three complexes paced from the right ventricular apex during ventricular tachycardia (VT) are shown; VT resumes on cessation of pacing. Fusion is not evident on the surface electrocardiogram because these complexes are identical to fully paced QRS complexes at the far right, yet fusion is present on the distal ablation recording (mid-diastolic potential at arrow seen during pacing as well). CL, Cycle length; PCL, pacing cycle length; His_{dist}, distal His bundle; His_{prox}, proximal His bundle; LV_{dist}, distal left ventricle; LV_{prox}, proximal left ventricle; LV_{uni}, unipolar left ventricle; RVA, right ventricular apex; RVOT, right ventricular outflow tract.

during entrainment will be identical to that of pacing in the absence of tachycardia (fully paced QRS or P wave) and no fusion.

When pacing is stopped, the impulse that conducts antidromically also conducts orthodromically to reset the reentrant circuit with orthodromic activation of the presystolic electrogram. When antidromic (retrograde) capture of the local presystolic electrogram occurs, the return cycle, even when measured at the site of the presystolic electrogram, exceeds the PCL by the difference in time from when the electrogram is activated retrogradely (i.e., preexcited antidromically) and when it would have been activated orthodromically.¹⁴

Postpacing Interval

The PPI is the time interval from the last pacing stimulus that entrained the tachycardia to the next nonpaced recorded electrogram at the pacing site (eFig. 5.4).

During entrainment from sites within the reentrant circuit, the orthodromic wavefront from the last stimulus propagates through the reentry circuit and returns to the pacing site, following the same path as the circulating reentry wavefronts. The conduction time required is the revolution time through the circuit. Thus the PPI (measured from the pacing site recording) should be equal (within 30 milliseconds) to the TCL, given that conduction velocities and the reentrant path did not change during pacing (see Fig. 5.16). At sites remote from the circuit, stimulated wavefronts propagate to the circuit, then through the circuit, and finally back to the pacing site. Thus the PPI should

equal the TCL (representing one complete revolution through the reentry circuit) plus the time required for the stimulus to propagate from the pacing site to the tachycardia circuit and back. Given that the TCL is stable (which is a prerequisite for entrainment assessment), and that there is no decremental conduction between the pacing site and the reentry circuit, the PPI should remain relatively stable when entrainment of a macroreentrant tachycardia is performed at the same site, regardless of the length of the pacing drive.

The greater the physical (or electrical) distance will be between the pacing site and the circuit, the longer the conduction time will be between the pacing site and reentry circuit, and the greater the difference is between the PPI and the TCL (PPI–TCL; see Figs. 12.12 and 13.7). The PPI–TCL value is highly reproducible during repeated entrainment attempts at the same PCL.^{19,20}

Several factors have to be considered when evaluating the PPI. The PPI should be measured to the near-field potential that indicates depolarization of tissue at the pacing site. However, assessment of the PPI can be problematic when the electrograms from the pacing site are not discernible, especially in regions of scar, where local near-field potentials are small and often difficult to distinguish or separate from far-field potentials. In addition, recordings of local activation at the pacing site may not be obtainable or interpretable due to electrical noise and signal saturation after the stimulus artifact. In these situations, the PPI can be measured from electrograms recorded by electrodes adjacent to those used for pacing (e.g., the proximal electrodes on the mapping catheter),

eFig. 5.4 Bystander Site During Left Atrial (LA) Flutter. The last three complexes of pacing from the posterior LA are shown in a patient with LA macroreentry. Although the timing of the electrogram at the pacing site is in early mid-diastole and the paced activation sequence is similar to tachycardia, thereby giving the appearance of an attractive ablation site, the results of entrainment indicate otherwise, with a large difference between the stimulus–coronary sinus (CS) electrogram interval (162 milliseconds) and the ablation recording–CS electrogram interval (45 milliseconds), as well as a large difference between the post-pacing interval (PPI) (425 milliseconds) and tachycardia cycle length (TCL, 320 milliseconds). *Abl_{dist}*, Distal ablation; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *PCL*, pacing cycle length; *TA_{dist}*, distal tricuspid annulus; *TA_{prox}*, proximal tricuspid annulus.

but this does introduce potential error, particularly in regions of abnormal conduction.¹³

It is important to recognize that the PPI–TCL value can be misleadingly long despite pacing from sites within the reentrant circuit. This is likely a result of rate-related decremental conduction in a zone of slow conduction within the reentry circuit, and is more likely to occur at rapid pacing rates or when the reentry circuit involves a slow conduction zone with a decremental conduction property such as the atrioventricular node (AVN). In one report in patients with typical atrial flutter (AFL), long PPI–TCL values (more than 30 milliseconds) after entrainment from the CTI were observed in 18% of patients despite a PCL within 20 milliseconds of the TCL, and more frequently when the PCL was more than 30 milliseconds shorter than the TCL and in patients on amiodarone therapy. The long PPI–TCL values are likely caused by rate-dependent slowing of conduction or alterations of the activation path. These findings likely also apply to other macroreentrant tachycardias.^{21–23}

On the other hand, an erroneously short PPI interval (shorter than the TCL) can result from far-field capture of downstream tissue distal to the local electrogram recorded at the pacing site. This results in shortening the path of the return cycle. A short PPI may also be encountered during delayed local capture, as indicated by latency between the stimulus artifact and local electrogram. In addition, transient acceleration of tachycardia can yield a seemingly short PPI.

In summary, the PPI–TCL value serves as an approximate measure of the distance from the pacing site to the reentry circuit. During pacing at a site that is in the circuit, the conduction time between the pacing site and the circuit is 0, and the PPI equals the TCL, provided that three fundamental assumptions are true. First, pacing must capture and entrain the tachycardia. Second, the electrograms used for measurement of the PPI are because of depolarization at the pacing site. Third, conduction through the reentry circuit must not be slowed or altered by pacing.^{22,24}

Stimulus–Electrocardiogram Complex Interval During Entrainment

During entrainment of reentrant tachycardia, the interval between the pacing stimulus and the onset of the tachycardia complex on the surface ECG (QRS or P wave) reflects the conduction time from the pacing site to the exit of the reentrant circuit (stimulus-exit interval), regardless of whether the pacing site is inside or outside the reentrant circuit. This is because activation starts at the pacing site and propagates in sequence to the circuit exit site.

Pacing from outer loop and remote bystander sites generates very short stimulus-exit intervals because the myocardium outside the circuit is directly activated by the pacing stimulus. In contrast, pacing from protected sites, such as the diastolic pathway (isthmus) of the reentry circuit or attached bystander or inner loop sites (communicating with the isthmus of the circuit and sharing the same exit) produces longer stimulus-exit intervals that reflect the conduction time from the pacing site through the protected pathway to the exit site of the circuit. Pacing from inner loop sites generates very long stimulus-exit intervals (>70% of TCL). On the other hand, pacing from the entrance, central isthmus, and exit site of the reentry circuit produces long (51% to 70% of TCL), intermediate (31% to 50% of TCL), and short (\leq 30% of TCL) stimulus-exit intervals, respectively.

During tachycardia, the interval between the local electrogram at a given mapping site and circuit exit site (electrogram-exit interval) can reflect the true conduction time between those two sites if they are activated in sequence (as occurs when the mapping site is located directly within the reentrant pathway), or it may be shorter than the true conduction time if those two sites are activated in parallel (which occurs

when the mapping site is located outside the reentrant circuit; see Fig. 5.16 and eFig. 5.4).^{13,19} Consequently, when mapping along the diastolic pathway of the reentry circuit, the electrogram-exit interval becomes progressively shorter as the mapping catheter is sequentially moved from the entrance toward the central isthmus and then the exit site of the circuit. Electrograms from the isthmus are generally fractionated and low amplitude, and occur during diastole resulting in early- (entrance), mid- (central), and late- (exit) diastolic (or presystolic) potentials. In contrast, mapping sites located at bystander sites attached to the isthmus of the circuit are activated in parallel with the exit site, resulting in a shortened electrogram-exit interval (i.e., a “pseudo-interval” that does not represent a true conduction time between the two locations).

Because a diastolic electrogram is not specific for the critical isthmus but can be recorded from bystander sites, comparing the stimulus-exit interval during entrainment to the electrogram-exit interval during tachycardia (both intervals are measured at the pacing site) can help distinguish the critical isthmus sites from attached bystander and non-dominant inner loop sites. At isthmus sites, activation from those sites to the exit of the circuit follows the same pathway during both tachycardia and entrainment. In contrast, attached bystander and nondominant inner loop sites are activated in parallel with the exit site during tachycardia but in sequence during entrainment, resulting in a significantly shorter (by more than 20 milliseconds) electrogram-exit interval than stimulus-exit interval. On the other hand, at any given pacing site, an electrogram-exit interval that is equal (\pm 20 milliseconds) to the stimulus-exit interval indicates that the pacing site lies within the reentry circuit and excludes the possibility that the site is a dead-end pathway attached to the circuit (i.e., not a bystander).

This measurement is essentially similar to PPI–TCL during concealed entrainment, but obviates some of the problems of PPI measurement since the electrogram-exit interval does not have to be measured in the first beat after pacing. However, the electrogram-exit interval may not be exactly equal to the stimulus-exit interval at sites within the reentrant circuit. Several factors can explain this. First, decremental conduction properties of the zone of slow conduction can potentially produce lengthening of the stimulus-exit interval during pacing; however, this appears to occur rarely, and can largely be obviated by measuring the stimulus-exit interval during pacing at the slowest PCL that reliably entrains the tachycardia. Second, stimulus latency in an area of diseased tissue can account for a delay in the stimulus-exit interval compared with the electrogram-QRS interval. Third, failure of the recording electrodes to detect low-amplitude depolarizations at the pacing site can account for a mismatch of the stimulus-exit and electrogram-exit intervals.¹⁹

This criterion helps verify the relationship of pacing sites demonstrating entrainment with concealed fusion to the reentry circuit. This measurement can produce conflicting results in cases of manifest ECG fusion or when the onset of the surface ECG complex (as is the case for many macroreentrant ATs) is not discernable. Therefore this criterion is of little value at pacing sites not exhibiting concealed fusion.¹⁷ This pitfall can be mitigated measuring the interval between the last stimulus entraining the tachycardia and a timing reference during the second beat after the stimulus (the N+1 beat), and then subtracting this interval from a comparable interval between the electrogram (at the pacing site) in any following beat (the so-called N+1 difference).

Number of Pacing Stimuli Needed to Entrain

As noted, the number of pacing stimuli required to entrain the reentrant circuit depends on the TCL, the duration of the excitable gap of the tachycardia, refractoriness at the pacing site, and the conduction time from the stimulation site to the reentrant circuit. Overdrive pacing

begins to advance a reentrant tachycardia precisely when the total pacing prematurity exceeds the PPI–TCL value after correcting for conduction velocity changes associated with the shorter PCL.¹⁵

The “number needed to entrain” assesses the number of captured pacing stimuli required to accelerate the tachycardia to the PCL. Recording electrograms at widely separated endocardial sites and properly timed initiation of the entrainment pacing (the coupling interval of the first paced stimulus is identical to the PCL) are required to measure the number needed to entrain. A short number of pacing stimuli needed to entrain indicates close proximity to the reentry circuit and agrees with a short PPI.²⁵

The number needed to entrain is associated with the time for the wavefront to reach the circuit. It becomes smaller at shorter PCLs (and greater TCL–PCL value) as the paced wavefronts arrive earlier to reentrant circuits. Therefore the number of pacing stimuli needed to entrain is predictable in proportion to the distance between the pacing site and reentrant circuit when the TCL–PCL value is taken into account.²⁵

A recent report evaluated this criterion in patients with macroreentrant AT. The number needed to entrain measured with a TCL–PCL value of 16 to 30 milliseconds is most accurate, where a number needed to entrain ≤ 2 is consistent with pacing site being within the reentry circuit, and greater than 3 is consistent with outside-the-circuit sites. Nevertheless, the number needed to entrain still has diagnostic value even when the TCL–PCL value did not fall within this range. A number needed to entrain ≤ 2 is highly specific for in-the-circuit for a TCL–PCL value of 5 to 15 milliseconds, whereas a number needed to entrain greater than 4 with a TCL–PCL value of 5 to 15 milliseconds and number needed to entrain greater than 3 with a TCL–PCL value of 31 to 50 milliseconds can exclude an in-the-circuit pacing site.²⁵

An advantage of this criterion is that it does not require continuation of tachycardia after pacing for assessment and remains valid even when the tachycardia terminates or changes. The number needed to entrain is also useful when electrograms for assessment of the PPI are difficult to define. Also, the number needed to entrain does not increase at shorter PCLs, likely because the conduction velocity in the intervening myocardium (between the pacing site and the reentry circuit) is less susceptible to changes in the PCL. This is in contrast to the slow conduction zone within the reentry circuit, which can display decremental conduction properties at PCLs shorter than the TCL, resulting in misleading long PPIs.²⁵

Mapping Procedure

Before attempting to use entrainment methods for mapping, it is necessary to demonstrate that the tachycardia can be entrained (fulfilling entrainment criteria discussed above), by providing strong evidence that it is caused by reentry rather than by triggered activity or automaticity. Proof of entrainment is best obtained by pacing from sites remote from the circuit, which most readily demonstrate manifest fusion.

Then, entrainment mapping is directed to sites identified by other mapping modalities, such as activation mapping and pace mapping, as potentially related to the reentrant circuit. These include areas of slow conduction (manifest as fractionated electrograms), sites with mid-diastolic electrograms, or those displaying long delays between the pacing stimulus and the captured surface ECG complex (see Fig. 5.16).

Entrainment mapping can be reliably carried out only if one can record and stimulate from the same area (e.g., for 2-5-2-mm spacing catheters, record from the second and fourth poles and stimulate from the first and third poles). Pacing is usually started at a PCL just shorter (10 to 20 milliseconds) than the TCL. Pacing should be continued for a long enough duration to allow for entrainment; short pacing trains are usually not helpful. Pacing is then repeated at progressively shorter PCLs.¹⁴

After cessation of each pacing drive, the presence of entrainment should be verified by demonstrating one or more of the entrainment criteria discussed previously. It is important to understand that the mere acceleration of the tachycardia to the pacing rate and then resumption of the original tachycardia after cessation of pacing do not establish the presence of entrainment. Evaluation of the PPI or other criteria is meaningless when the presence of true entrainment has not been established. Moreover, it is important to verify the absence of termination and reinitiation of the tachycardia during the same pacing drive.

Once the presence of entrainment is verified, several criteria can be used to indicate the relation of the pacing site to the reentrant circuit (Fig. 5.21). The first entrainment criterion to be sought is concealed fusion. Entrainment with concealed fusion indicates that the pacing site is in a protected isthmus located within or attached to the reentrant circuit. Whether this protected isthmus is crucial to the reentrant circuit or is just a bystander site needs to be verified by other criteria, mainly comparing the PPI with the TCL and comparing the stimulus-exit interval with the electrogram-exit interval. Furthermore, the ratio of the stimulus-exit interval to the TCL can provide information regarding the location of the pacing site within the diastolic pathway of the reentry circuit. Long (51% to 70% of TCL), intermediate (31% to 50% of TCL), and short ($\leq 30\%$ of TCL) stimulus-exit intervals are observed during pacing from the entrance, central isthmus, and exit site of the reentry circuit, respectively. Features of entrainment when pacing from different sites are listed in Box 5.2 (see Figs. 5.16, 5.20, and eFig. 5.4).¹⁹

A graphical representation of entrainment mapping can be constructed by plotting the PPI–TCL values on an electroanatomical mapping system (CARTO, Biosense Webster, Diamond Bar, CA, United States; or NavX, St. Jude Medical, St. Paul, MN, United States) to generate color-coded three-dimensional entrainment maps (see Chapter 6 for discussion).^{26,27}

Clinical Implications

1. **CONFIRMATION OF REENTRY AS THE TACHYCARDIA MECHANISM.** Achievement of entrainment of a tachycardia establishes

BOX 5.2 Entrainment Mapping of Reentrant Tachycardias

Pacing From Sites *Outside* the Reentrant Circuit (Remote Bystanders)

- Manifest fusion on surface ECG or intracardiac recordings
- PPI–TCL > 30 ms

Pacing From Sites *Outside* the Reentrant Circuit (Attached Bystanders)

- Concealed fusion
- PPI–TCL > 30 ms
- Stimulus-exit interval $>$ electrogram-exit interval

Pacing From Sites *Inside* the Reentrant Circuit (Outer Loop)

- Manifest fusion on surface ECG or intracardiac recordings
- PPI–TCL < 30 ms

Pacing From a Protected Isthmus *Inside* the Reentrant Circuit

- Concealed fusion
- PPI–TCL < 30 ms
- Stimulus-exit interval = electrogram-exit interval (± 20 ms)

reentry as the mechanism of the tachycardia and excludes triggered activity and abnormal automaticity as potential mechanisms. Furthermore, entrainment with fusion excludes microreentry, and establishes the diagnosis of macroreentry (with spatially separate entrance and exit sites).¹³

2. **APPROXIMATION OF THE LOCATION OF THE REENTRANT CIRCUIT.** Entrainment is commonly used to estimate how far the reentrant circuit is from the pacing site qualitatively. Pacing at multiple sites and measuring the difference between the *PPI* and *TCL* provide an indication of how far or near the pacing site is from the circuit (Fig. 5.22). The smaller the *PPI*–*TCL* value, the closer the pacing site to the reentry circuit. For example, entrainment of an

AT from multiple sites in the RA with a *PPI* significantly longer than the *TCL* can help identify an LA origin of the AT before attempting LA access (see Fig. 13.7).^{19,28}

3. **IDENTIFICATION OF THE CRITICAL ISTHMUS OF THE REENTRANT CIRCUIT.** Entrainment mapping is the gold standard for ablation of reentrant circuits generating hemodynamically well-tolerated tachycardias (macroreentrant VT or AT). Focal ablation of all sites defined as within the reentrant circuit may not result in a cure of reentrant tachycardia. Cure requires ablation (transection) of an isthmus bordered by barriers on either side, which is critical to the reentrant circuit. Entrainment mapping helps identify this critical part of the reentrant circuit to guide ablation. Sites

Fig. 5.22 The Postpacing Interval (PPI). PPI-TCL interval as an indicator of distance from the pacing site to the reentrant circuit (located in the dome of the left atrium [LA], near 10). demonstrating entrainment with concealed fusion are initially sought. Once these sites are identified, their relationship to the reentrant circuit is verified using the PPI or stimulus-exit interval (see earlier). Sites demonstrating (1) concealed fusion, (2) PPI equal to the TCL (± 30 milliseconds), and (3) stimulus-exit interval equal to the electrogram-exit interval (± 20 milliseconds) have a very high positive predictive value for successful ablation.¹³

Limitations

One of the limitations of entrainment mapping is the requirement of the presence of sustained, hemodynamically well-tolerated tachycardia of stable morphology and TCL. Furthermore, attempts at entrainment can result in termination, acceleration, or transformation of the index tachycardia into a different one, thus making further mapping challenging. Bipolar pacing at relatively high stimulus strengths used during entrainment can result in the capture of an area larger than the local area, decreasing the specificity of the results.

Errors can be introduced by the decremental conduction properties of the zone of slow conduction that may cause a rate-dependent lengthening of the PPI. This is more likely to occur at rapid pacing rates or when the reentry circuit involves a slow conduction zone with a decremental conduction property such as the AVN.^{21–23}

An erroneously short PPI interval (shorter than the TCL) can result from far-field capture of myocardium tissue distal to the local electrogram recorded at the pacing site or delayed local capture. Therefore the differentiation between near- and far-field responses during pacing is critical to entrainment mapping.

Pacing and recording from the same area are required for entrainment mapping. This requirement is usually satisfied by pacing from electrodes 1 and 3 and recording from electrodes 2 and 4 of the mapping catheter. However, this technique has several limitations:

1. There are differences, albeit slight, of the area from which the second and fourth electrodes record as compared with the first and third. When the local electrogram is not recorded from the same pair of electrodes used for pacing, errors can be introduced when comparing the PPI with the TCL.

2. The bipolar pacing technique has the potential for anodal (proximal electrode) contribution to local capture.
3. The total area captured by the pacing stimulus can exceed the local area from which the electrogram is recorded, especially when high currents (more than 10 mA) are required for stimulation.
4. The pacing artifact can obscure the early part of the captured local electrogram. In such a case, a comparable component of the electrogram can be used to measure the PPI.
5. Far-field electrical signals generated by depolarization of adjacent tissue can cause false-positive entrainment criteria at some sites.¹⁷

As noted, the “number needed to entrain” criterion can overcome some of the disadvantages mentioned above, since it does not require continuation of tachycardia after pacing and is not affected by decremental conduction properties within the reentrant circuit.²⁵

PACE MAPPING

Fundamental Concepts

Pace mapping is a technique designed to help locate tachycardia sources by pacing at different endocardial sites to reproduce the ECG morphology of the tachycardia. Pace mapping is based on the principle that pacing from the site of origin of a focal tachycardia at a PCL similar to the TCL results in the same activation sequence as that during the tachycardia.

When myocardial activation originates from a point-like source, such as during focal tachycardia or during pacing from an electrode catheter, ECG configuration of the resultant tachycardia or paced complex (QRS or P wave) is determined by the sequence of myocardial activation, which is largely determined by the initial site of myocardial depolarization, assuming no conduction abnormalities from that site. Analysis of specific surface ECG configurations in multiple leads allows for the estimation of the pacing site location to within several square centimeters, and comparing the paced complex configuration with that of tachycardia can be used to locate the arrhythmia focus (eFig. 5.5). However, differences in spatial resolution within different cardiac chambers has been demonstrated.²⁹

On the other hand, reentry circuits in healed infarct scars often extend over several square centimeters and can have a variety of configurations. In many circuits, the excitation wavefront circulates through surviving myocytes within the scar, the depolarization of which is not detectable on the standard surface ECG. The QRS complex is then inscribed after the reentry wavefront exits the scar and propagates across the ventricles. At sites at which the reentrant wavefront exits the scar, pace mapping is expected to produce a QRS configuration similar to that of the VT (Fig. 5.23). Pace mapping at sites more proximally located in the isthmus should also produce a similar QRS complex, but with a longer S-QRS interval. The S-QRS interval lengthens progressively as the pacing site is moved along the isthmus, consistent with pacing progressively farther from the exit.

In infarct-related VT, however, a paced QRS configuration different from that during VT does not reliably indicate that the pacing site is distant from the reentry circuit. At many reentry circuit sites, pacing during NSR can produce a QRS configuration different from that during VT. It is rather uncommon to have similar or even almost identical morphology result from pacing from a known isthmus determined by mapping. Several factors can explain this mismatch. First, the pattern of ventricular activation and hence resultant QRS depends on how the wavefront propagates from the exit of the isthmus to the remainder of the heart, which can be totally different during VT than during pacing from the same site during NSR (see Fig. 5.23). In fact, such pacing would be expected to produce a different QRS than the VT because the paced wavefront may spread roughly centrifugally to the heart while

eFig. 5.5 Pace Mapping of Ventricular Tachycardia (VT). At left, 12 electrocardiogram (ECG) leads and intracardiac recordings during idiopathic right ventricular outflow tract VT are shown (cycle length [CL], 280 milliseconds). At right, pace mapping from the site of earliest ventricular activation at CL 350 milliseconds produces an identical 12-lead ECG configuration (the VT complex superimposed on the first paced complex). *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *RVA*, right ventricular apex.

Fig. 5.23 Pacing to Verify Ablation Sites in Reentrant Ventricular Tachycardia (VT). (A) Five electrocardiogram leads of VT are shown with a figure-of-eight circuit with propagation of the reentrant wavefront (arrows); the protected diastolic corridor is also shown (short straight arrow). (B) Pacing is performed during VT from a site near the entrance to the diastolic corridor (asterisk); the impulse must traverse a significant slow conduction zone before exiting to generate a QRS complex, resulting in a long S-QRS as shown. (C) Pacing is performed at the same site as in B, but during sinus rhythm; the impulse exits in the opposite direction from B because it takes less time to propagate in this direction (short S-QRS). The resulting QRS complex is completely different, despite pacing at the same site. (D) Pacing is performed during sinus rhythm from a site closer to the exit of the diastolic corridor. The QRS is the same as VT because the path taken is the same as in VT, and the S-QRS is short. NSR, Normal sinus rhythm; RV, right ventricle.

the VT wavefront spreads in one direction (i.e., orthodromically). This observation is one of the important limitations of the use of pace mapping to identify the critical isthmus of post-MI VT. Propagation in the diseased myocardium is not homogeneous, and small differences in catheter location can cause grossly different propagation wavefronts and resultant QRS complexes. Even small differences in the angle of contact of catheter to the ventricular wall and site of initial ventricular activation can alter the precise QRS configuration. The relationship between conduction time, pacing site location in the isthmus, and conduction block determines whether pace mapping in an isthmus produces a QRS that resembles that of VT. When pace mapping in a defined isthmus is performed, the stimulated wavefront can only follow along its course, which occurs in at least two directions—orthodromic and antidromic (relative to the direction of VT propagation). The wavefront

is only detected on the surface ECG when it leaves this protected channel. If the isthmus is long and the catheter is positioned in the distal part, near the exit, the orthodromic wavefront leaves the exit and rapidly depolarizes the region along the infarct, colliding with and preventing emergence of the antidromic wavefront from the infarct region. The resulting QRS complex is then similar to that of VT. If the isthmus is short, or the catheter is positioned more proximally, the stimulated antidromic wavefront leaves the protected isthmus at the entrance, propagating to the surrounding myocardium and producing a different QRS morphology (see Fig. 5.23). If the orthodromic wavefront reaches the exit, a fusion QRS is produced that includes depolarization from both the antidromic and orthodromic wavefronts.

A second explanation is that the process whereby VT is generated in patients with structural heart disease usually involves the development

of an area of functional block to conduction. Such functional block, by definition, is not fixed and varies in its extent. When formed, it combines with an area of fixed conduction block caused by, for example, the infarct scar, to create a protected channel for conduction that allows reentry to occur. Regions of functional block, present during VT, can define propagation paths during tachycardia but not during pace mapping in NSR. Therefore, if block defining an isthmus is present only during VT and is absent during pace mapping in NSR, the stimulated wavefront produced by pacing at the isthmus site would propagate in all directions, resulting in a different QRS morphology (see Fig. 22.26). This is further exaggerated by the fact that pace mapping is usually performed at rates slower than the VT to avoid VT induction during the mapping process, which can reduce the likelihood of development of a line of functional block. In addition, the area over which the current is delivered, especially where high current is required for relatively inexcitable tissue, can influence the pattern of subsequent ventricular activation, presumably by capturing more distant (far-field) tissue. When this occurs, it can indicate pacing in a region of a protected isthmus, where pacing at low output would capture only the isthmus, whereas pacing at a higher output can capture both the isthmus and far-field tissue, resulting in different QRS morphologies and S-QRS intervals (see Fig. 22.27). Finally, some circuits can have more than one exit, with wavefronts emerging from the scar at multiple locations. Different exits can participate preferentially during VT but not during pace mapping, and vice versa.

On the other hand, pacing during NSR from sites attached to the reentrant circuit but not part of the circuit can occasionally produce QRS morphology identical to that of the VT, because the stimulated wavefront can be physiologically forced to follow the same route of activation as the VT as long as pacing is carried out between the entrance and exit of the protected isthmus. Although this strategy can result in

the identification of irrelevant nondominant inner loop and adjacent bystander sites as well as the desired isthmus sites, it still can be helpful in gross identification of the region of the VT circuit.

Conduction away from the pacing site (and the resultant QRS morphology) potentially can be influenced by the pacing output, pacing rate, and antiarrhythmic drugs. To minimize the impact of rate-related changes in conduction, pacing is performed at a relatively slow rate. Pacing slower than the rate of the VT, however, can further reduce the relationship of the paced QRS morphology to that of the VT target area. During bipolar pacing, capture at the proximal electrode (anode) rather than uniquely at the distal electrode can also modify the QRS morphology. Further, the sequence of ventricular activation can vary during pacing at different stimulus strengths. This phenomenon is more pronounced with bipolar than unipolar pacing, likely because of anodal capture at higher stimulus strengths (see Fig. 22.25). This potential problem can be avoided by using unipolar pacing and by limiting the current output to 10 mA and 2 milliseconds, which is within the range of routine programmed stimulation.

The same principles used in pace mapping in VT apply to AT, but in this case, matching of a paced intracardiac activation sequence with that of tachycardia is used. This is because while the P wave can be difficult to discern on the ECG, it is possible to have a large number of electrode recordings representing much of the atrial mass, with which to compare paced versus tachycardia activation sequences.

Pace Map Matching

The greater the degree of concordance between the morphology during pacing and that during tachycardia, the closer the catheter will be to the site of origin of the tachycardia. Pace maps with identical or nearly identical matches of the tachycardia morphology in all 12 surface ECG leads can be indicative of the site of origin of the tachycardia (Fig. 5.24).

Fig. 5.24 Pace Mapping of Right Ventricular Outflow Tract Tachycardia. Pace mapping at various sites in the right ventricular outflow tract produces QRS configurations (A to D) with less or more similarity to the ventricular tachycardia (VT) QRS (left panel); E shows an exact match. *Abl_{dist}*, Distal ablation; *Abl_{prox}*, proximal ablation; *RVA*, right ventricular apex.

Differences in the morphology between pacing and spontaneous tachycardia in a single lead can be critical. For VT, pacing at a site 5 mm from the index pacing site results in minor differences in QRS configuration (e.g., notching, new small component, change in amplitude of individual component, or overall change in QRS shape) in at least one lead in most patients. In contrast, if only major changes in QRS morphology are considered, pacing sites separated by as much as 15 mm can produce similar QRS morphologies.

Although qualitative comparison of the 12-lead ECG morphology between a pace map and VT is frequently performed, there are few objective criteria for quantifying the similarity between two 12-lead ECG waveform morphologies. Such comparisons are frequently completely subjective or semiquantitative, such as a “10/12 lead match.” Discrepancies in VT ablation outcome can result, in part, from subjective differences in opinion regarding the closeness of a pace map match to the clinical VT. In addition, a common human error in analyzing a pace map is not appreciating subtle amplitude or precordial lead transition differences between two ECG patterns.

To overcome these limitations, two mathematical waveform comparison metrics, the correlation coefficient (CORR) and the mean absolute deviation (MAD), have been developed to quantify the similarity of 12-lead ECG waveforms during VT/PVC and pace mapping objectively.

It has been suggested that an automated objective interpretation can have some advantage to qualitative interpretation. Although CORR is more commonly used, MAD is more sensitive to differences in waveform amplitude. The MAD score grades 12-lead ECG waveform similarity as a single number ranging from 0% (identical) to 100% (completely different). A MAD score of up to 12% was 93% sensitive and 75% specific for a successful ablation site (eFig. 5.6). It is not surprising that the MAD score is more sensitive than specific; characteristics other than a 12-lead ECG match are necessary for successful ablation, including catheter-tissue contact, catheter orientation, and tissue heating.

More recently, an automated waveform comparison algorithm using CORR has been implemented in the Boston Scientific LabSystem PRO EP recording system (Boston, MA, United States) (Fig. 5.25). A template matching software is also currently available and integrated into the CARTO 3-D mapping systems (PaSo, Biosense Webster) (Fig. 5.26). These automated algorithms process digital images to match the target QRS complex (template signal) and the paced QRS complex (test signal), and they provide a score according to the similarity between the two QRS morphologies. The software “slides” the reference over the incoming data until the best local match is found by using a correlation calculation. For each lead-to-lead comparison, both the polarity and

Fig. 5.25 Automated Pace Map Matching. Pace mapping using an automated waveform comparison algorithm implemented in the Boston Scientific LabSystem PRO EP recording system (Boston, MA, United States). *Left*, Surface 12-lead electrocardiogram (ECG) QRS morphology of the spontaneous premature ventricular complex (PVC) is saved as a template. *Middle*, A score is calculated (yellow numbers) according to QRS morphology similarity between the template PVC morphology (red) and the paced QRS morphology (white) in each surface ECG lead, and is averaged at 99%, indicating an almost perfect pace match. *Right*, Pace match is averaged at 95%, with the largest discrepancy occurring in lead I (QRS similarity of only 67%).

eFig. 5.6 The Mean Absolute Deviation (MAD) Score. (A) Example of right ventricular outflow tract (RVOT) ventricular tachycardia (VT). The second VT complex has been identified as the target waveform by the annotation markers placed on either side of this complex. (B) Pace map from a free wall site 1 (FW1) next to the superimposed VT and pace map waveforms after automatic computer alignment. There are substantial differences between these two waveforms (highlighted in gray), resulting in an MAD score of 31.5%. (C) Pace map from the successful ablation site (Abl S) near the posterior septum and the superimposed pace map and VT waveform. Note in the Abl S panel that when these two waveforms are aligned they are nearly superimposable, and result in a very low MAD score of 5.3%. Correlation coefficients for these comparisons are also shown. (From Gerstenfeld EP, Dixit S, Callans DJ, et al. Quantitative comparison of spontaneous and paced 12-lead electrocardiogram during right ventricular outflow tract ventricular tachycardia. *J Am Coll Cardiol.* 2003;41:2046.)

Fig. 5.26 Automated Pace Mapping Integrated Into the Electroanatomical Mapping System. *Left panels* (A and C), The template matching software integrated into the CARTO-3 mapping systems (PaSo, Biosense Webster, Diamond Bar, CA, United States) processes digital images to match the premature ventricular complex (PVC) QRS complex (green) and the paced QRS complex (yellow), and provides a score between 0 and 1 (blue numbers) according to the similarity between the two QRS morphologies. *Right panels* (B and D), CARTO electroanatomical activation map (color-coded) of the focus of the PVCs in the right ventricular outflow tract (anterior view). *Upper panels* (A and B), Pacing performed from the tip of the ablation catheter (visualized on the activation map) about 18 mm away from the site of earliest local activation (red on the activation map) produced a paced QRS morphology with an 80% pace match. *Lower panels* (C and D), Pacing closer to the site of earliest local activation resulted in a higher degree of degree of correlation (98%).

Fig. 5.27 Pace Map Matching in Focal Atrial Tachycardia. (A) Intracardiac activation sequence during a focal inferolateral right atrial tachycardia. (B) Pacing at the site with the earliest local activation time shows a nearly exact match with tachycardia (superimposed in red) in intracardiac recordings. P wave matching is more problematic. *Abl D*, Distal ablation; *Abl P*, proximal ablation; *Abl uni*, unipolar ablation; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HIS D*, distal His bundle; *HIS M*, middle His bundle; *HIS P*, proximal His bundle; *TA_{dist}*, distal tricuspid annulus; *TA_{prox}*, proximal tricuspid annulus.

the amplitude of the QRS complexes play an important role as to the resulting value of the percentage of correlation calculated by the software. The site that yields the highest average correlation (value toward 99% to 100%) across all of ECG leads means a perfect match between two 12-lead ECG morphologies. Generally, an average template-matching score above 90% is considered sensitive for the identification of successful versus unsuccessful ablation sites. The Boston Scientific LabSystem PRO also has an algorithm for matching intracardiac activation sequences, but its performance does not seem as good as the QRS matching algorithm (Fig. 5.27).^{30–32}

Stimulus–QRS Interval During Pace Mapping

Ventricular pacing in normal myocardium is associated with an S–QRS interval shorter than 20 milliseconds. On the other hand, an S–QRS interval longer than 40 milliseconds is consistent with slow conduction from the pacing site and is typically associated with abnormal fractionated electrograms recorded from that site during sinus rhythm. Thus pace mapping can provide a measure of slow conduction, as indicated by the S–QRS interval. It is likely that pacing sites with long S–QRS delays are in an isthmus adjacent to regions of conduction block. However, this isthmus can be part of the reentrant circuit or a bystander.

For post-MI VTs, at sites at which the reentrant wavefront exits the scar, pace mapping is expected to produce a QRS configuration similar to that of the VT. Pace mapping at sites located more proximally in the isthmus should also produce a similar QRS complex, but with a longer S–QRS interval. The S–QRS interval lengthens progressively as the pacing

site is moved along the isthmus, a finding consistent with pacing progressively farther from the exit. Therefore parts of VT reentry circuit isthmuses can be traced during NSR by combining both the QRS morphology and the S–QRS delay from pace mapping in anatomical maps. This works well when pacing is performed during tachycardia, at which time wavefront propagation is constrained in one direction through a corridor bounded by barriers that can be anatomically or functionally determined. However, pace mapping at the same sites during sinus rhythm can yield different results because the barriers may not exist then, and the preferential direction of propagation may not be the same as during tachycardia. This is especially true for pacing at circuit entrance sites (see Fig. 5.23).

When pacing during sinus rhythm at sites within a protected isthmus area, as the electrode is moved more proximally (relative to the direction of propagation during VT), the paced QRS complex matches that of VT but the S–QRS interval progressively increases. As the pacing site continues to move, when there is an abrupt change in QRS configuration, the site at which this occurs has been correlated with an attractive ablation site, indicating that the pacing site is now closer to another outlet from the isthmus (the entrance) than it is to the exit. A corollary of this is the so-called multiple exit site phenomenon, in which continued pacing from one location (at the same or varied outputs) yields two or more QRS morphologies (eFig. 5.7). Ablation at such sites may eliminate multiple VT morphologies that use the same isthmus, but with either different exit sites or different directions of propagation in the isthmus.

eFig. 5.7 Pacing at One Site Within Scar Yields Different QRS Configurations. Stimulation at the same site throughout the figure shows different QRS configurations, with a similar delay from stimulus to QRS onset. *Abl D*, Distal ablation; *Abl P*, proximal ablation; *HIS D*, distal His bundle; *HIS M*, middle His bundle; *HIS P*, proximal His bundle; *RVA p*, right ventricular apex.

Mapping Procedure

Initially the exact morphology of the tachycardia complex should be determined and used as a template for pace mapping. For VT, QRS morphology during the tachycardia should be inspected in all 12 surface ECG leads. For AT, determining the morphology of the P wave during the tachycardia can be challenging, and proper interpretation of discrete changes in P wave shape is limited by its low voltage and distortion or masking by the superimposed ST segment and T wave. Therefore the P wave during AT should be assessed using multiple ECG leads in addition to the intracardiac electrogram activation sequence. Delivery of a VES (or a train of ventricular pacing) to advance ventricular activation and repolarization can allow careful distinction of the P wave onset and morphology. Paced activation sequence mapping can be used as an alternative to P-wave morphology, but requires the use of multiple electrodes (e.g., Halo and CS catheters) to assess atrial activation sequence.

Pace mapping during tachycardia (at a PCL 20 to 40 milliseconds shorter than the TCL) is preferable whenever possible, because it facilitates rapid comparison of tachycardia and paced complexes at the end of the pacing train in a simultaneously displayed 12-lead ECG. If only nonsustained tachycardia or ectopic beats are inducible, pacing is performed during NSR. In this setting, the PCL and coupling intervals of the extrastimuli should match those of spontaneous ectopy. This seems to be more relevant for ventricular arrhythmias. For ATs, pacing at exactly the TCL does not seem as critical to reproduce a similar atrial sequence.

Pace mapping is preferably performed with unipolar stimuli (≤ 10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the inferior vena cava (anode), or with closely spaced bipolar pacing at twice diastolic threshold to eliminate far-field stimulation effects.

The resulting 12-lead ECG morphology is compared with that of the tachycardia. ECG recordings should be reviewed at the same gain and filter settings, and at a paper-sweep speed of 100 mm/sec. It is often helpful to display all 12 ECG leads side by side in review windows on screen, as well as a printout of regular 12-lead ECGs for side-by-side comparison on paper. The greater the degree of concordance between the morphology during pacing and tachycardia, the closer the catheter will be to the site of origin of the tachycardia. Exact concordance occurring in 12 of 12 leads on the surface ECG is predictive of the site of origin of the tachycardia. Also, automated waveform comparison algorithms offer a significant advantage for template matching during pace mapping.³³

For mapping macroreentrant VT circuits, it is important to evaluate the S-QRS interval, the interval from the pacing stimulus to the onset of the earliest QRS on the 12-lead ECG. The reentry circuit exit, which is more likely to be at the border of the infarct and close to the normal myocardium, often has a short S-QRS interval during pace mapping during NSR, even though it is a desirable target for ablation. A delay between the pacing stimulus and QRS onset is consistent with slow conduction away from the pacing site; this can indicate a greater likelihood that the pacing site is in a reentry circuit. This method can be useful for initially screening sites during NSR.

Clinical Implications

Pace mapping is used as an adjunct to other methods of mapping to corroborate putative ablation sites. It can be of great help, especially when the tachycardia is difficult to induce. Although there are some limitations to this technique, many studies have demonstrated efficacy using pace mapping to choose ablation target sites. The highest benefit of pace mapping has been found in focal tachycardias, especially in idiopathic VT. Pace mapping of focal ATs is more limited due to

difficulties in precisely comparing P wave morphologies, and intracardiac activation sequences limit the applicability of pace mapping.

For macroreentrant VT, pace mapping remains at best a corroborative method of localizing the isthmus critical to the reentrant circuit. It can be used to focus initial mapping efforts to regions likely to contain the reentrant circuit exit or abnormal conduction, but it is sufficiently specific or sensitive to be the sole guide for ablation. Pace mapping can also be used in conjunction with substrate mapping when other mapping techniques are not feasible. Pace mapping has advantages over activation mapping in that induction of VT is not required; thus it allows for the identification of the site of origin when the induced VT is poorly tolerated or when VT is not inducible by EP techniques but the QRS morphology from a prior 12-lead ECG during VT is available.

Limitations

An optimal spatial pace mapping resolution requires a short maximum distance between two points generating a similar ECG configuration. Usually the spatial resolution is best for unipolar stimulation, and deteriorates with large electrodes, bipolar stimulation, and pacing at pathological areas. Spatial resolution worsens with bipolar stimulation by inducing electrical capture at both electrodes with variable contribution of the proximal electrode (anode) to depolarization. Such changes in paced ECG morphology that are potentially induced by bipolar pacing can be minimized by low pacing outputs and a small interelectrode distance (5 mm or less). Importantly, the rapid electrical propagation within the right ventricular outflow tract (RVOT) limits the spatial resolution of pace mapping. In one report, the spatial resolution of a good pace map for targeting RVOT VT was about 1.8 cm² and was inferior to that of an activation map for locating the exact site of origin at which ablation would eradicate the arrhythmia.³⁴

Current strengths up to 10 mA have little effect on unipolar paced ECG configuration. In contrast, bipolar pacing can introduce some variability in the paced ECG; a significantly large amount of local myocardium is captured, which, combined with varying degrees of anodal capture, can be detrimental to mapping accuracy.

It is important to understand that the morphology of single paced complexes can vary, depending on the coupling interval, and the paced complex morphology during overdrive pacing is affected by the PCL. Therefore the coupling interval or TCL of the template arrhythmia should be matched during pace mapping, especially during mapping of isolated PVCs. In this case, a single VES at a coupling interval matching that of the PVC can provide a more accurate match than fixed-rate pacing at the same site (Fig. 5.28). Also, spontaneous couplets from the same focus can have slight variations in QRS morphology that must be considered when seeking a pace match.

Pace mapping during post-MI VT has several other limitations. Some areas of conduction block are not anatomically determined but can be functional. Therefore pacing within the diastolic corridor of the VT circuit during NSR can generate a completely different QRS complex from that of the VT (see Fig. 5.24). Consequently, during pace mapping, a QRS configuration different from VT does not reliably indicate that the pacing site is distant from the reentry circuit. On the other hand, pacing during NSR from sites attached to the reentrant circuit but not part of the circuit can occasionally produce a QRS morphology identical to that of the VT. At best, a pace map that matches the VT would identify only the exit site to the normal myocardium, and this site can be distant from the critical sites of the circuit required for ablation.

VIDEOS

The following video accompanies this chapter:

See Video 3.1. Reentrant Ventricular Tachycardia: Optical Mapping. 

Fig. 5.28 Use of Ventricular Extrastimuli (VES) as Opposed to Fixed-Rate Pacing When Matching Morphology of a Premature Ventricular Complex (PVC). (A) The target PVC is shown that has a coupling interval from the prior QRS 460 milliseconds. (B) Fixed-rate pacing is performed at a site of presystolic activation; the match with the PVC (superimposed in red) is good but not perfect. (C) A single VES delivered at the same site with the same coupling interval as the PVC yields a much better match with the PVC.

Conventional radiofrequency (RF) ablation has revolutionized the treatment of many supraventricular as well as ventricular arrhythmias. Success in stable arrhythmias with predictable anatomical locations or characteristics identifying endocardial electrograms, such as idiopathic ventricular tachycardia (VT), atrioventricular nodal reentrant tachycardia (AVNRT), atrioventricular reentrant tachycardia (AVRT), or typical atrial flutter (AFL), has approached 90% to 99%. However, as interest has turned to a broad array of more complex arrhythmias, including some atrial tachycardias (ATs), many forms of intraatrial reentry, most VTs, and atrial fibrillation (AF), ablation of such arrhythmias continues to pose a major challenge. This stems in part from the limitations of fluoroscopy and conventional catheter-based mapping techniques to localize arrhythmogenic substrates that are removed from fluoroscopic landmarks and the lack of characteristic electrographic patterns for ablation targets.

The use of fluoroscopy for these purposes can be problematic for several reasons: (1) intracardiac electrograms cannot be associated accurately with their precise location within the heart; (2) the endocardial surface is invisible using fluoroscopy, and target sites may be approximated only by their relationship with nearby structures, such as ribs, blood vessels, and the position of other catheters; (3) fluoroscopy-guided catheter navigation is not exact, is time-consuming, and requires multiple views to estimate the three-dimensional (3-D) location of the catheter; (4) the catheter cannot accurately and precisely be returned to a previously mapped site; and (5) the patient and medical team are exposed to radiation.

Newer mapping systems have transformed the clinical electrophysiology (EP) laboratory, have enabled physicians to overcome some of the limitations of conventional mapping, and have offered new insights into arrhythmia mechanisms. These systems are aimed at improving

mapping resolution, 3-D spatial localization, and rapidity of acquisition of cardiac activation maps. The application of these various techniques for mapping specific arrhythmias is described elsewhere in this text, as are the details of the diagnosis, mapping, and treatment of specific arrhythmias.

However, to date, the integration of anatomical, EP, and software information by an experienced physician is an indispensable prerequisite to accomplish a safe and successful procedure. At most, such systems must be used as an adjunctive tool to facilitate mapping and ablation. The operator should understand the advantages and shortcomings of each system, and should recognize that these systems can be misleading and confusing, providing inaccurate information as a result of either incorrect data acquisition or inherent limitations of the technology.¹

ELECTROANATOMIC MAPPING

Electroanatomic mapping systems use novel approaches to determine the 3-D location of the mapping catheter accurately, while local electrograms are acquired using conventional methods. Recorded data of the catheter location and associated intracardiac electrogram at that location are used to reconstruct in real time a representation of the 3-D geometry of the cardiac chamber, color-coded with relevant EP information (local activation time and electrogram amplitude), as well as purely anatomical chamber mapping.

At the present time, three electroanatomic mapping systems are in clinical use: (1) CARTO (Biosense Webster, Diamond Bar, CA, United States); (2) EnSite NavX (St. Jude Medical, St. Paul, MN, United States); and (3) Rhythmia (Boston Scientific, Cambridge, MA, United States). These systems use electromagnetic or impedance-based catheter location methods, or a hybrid of both.¹

Fundamental Concepts

CARTO Electroanatomic Mapping System

The CARTO mapping system consists of an ultralow magnetic field emitter, a magnetic field generator locator pad (placed beneath the operating table), an external reference patch (fixed on the patient's back), a deflectable 7 Fr quadripolar mapping-ablation catheter with a 4- or 8-mm tip and proximal 2-mm ring electrodes, location sensors inside the mapping-ablation catheter tip (the three location sensors are located orthogonally to each other and lie just proximal to the tip electrode, totally embedded within the catheter), a reference catheter, a data processing unit, and a graphic display unit to generate the electroanatomic model of the chamber being mapped.²

The CARTO electroanatomic mapping is based on the premise that a metal coil generates an electrical current when it is placed in a magnetic field. The magnitude of the current depends on the strength of the magnetic field and the orientation of the coil in it. The CARTO mapping system uses a triangulation algorithm similar to that used by a global positioning system (GPS). The magnetic field emitter, mounted under the operating table, consists of three coils that generate a low-intensity magnetic field (5×10^{-6} to 5×10^{-5} T) that is a very small fraction of the magnetic field intensity inside a magnetic resonance imaging (MRI) machine (Fig. 6.1).²

The sensor embedded proximal to the tip of a specialized mapping catheter detects the intensity of the magnetic field generated by each coil and allows for the determination of its distance from each coil. These distances determine the area of theoretical spheres around each coil, and the intersection of these three spheres determines the exact position and orientation of the tip of the catheter, in relation to a reference sensor on the skin. The accuracy of the determination of the location is highest in the center of the magnetic field; therefore it is important to position the location pad under the patient's chest. In

addition to the x , y , and z coordinates of the catheter tip, the CARTO system can determine three orientation determinants—roll, yaw, and pitch—for the electrode at the catheter tip. The position and orientation of the catheter tip can be seen on the screen and monitored in real time as the catheter moves within the electroanatomic model of the chamber mapped. The catheter icon has four color bars (green, red, yellow, and blue), enabling the operator to view the catheter as it turns clockwise or counterclockwise. In addition, because the catheter always deflects in the same direction, each catheter will always deflect toward a single color. Hence, to deflect the catheter to a specific wall, the operator should first turn the catheter so that this color faces the desired wall.²

The unipolar and bipolar electrograms recorded by the mapping catheter at each endocardial site are archived within that positional context. Using this approach, local tissue activation at each successive recording site produces activation maps within the framework of the acquired surrogate geometry.

When mapping the heart, the system can deal with four types of motion artifacts: cardiac motion (the heart is in constant motion; thus the location of the mapping catheter changes throughout the cardiac cycle), respiratory motion (intrathoracic change in the position of the heart during the respiratory cycle), patient motion, and system motion. Several steps are taken by the CARTO mapping system to compensate for these possible motion artifacts, and to ensure that the initial map coordinates are appropriate, including using a reference electrogram and an anatomical reference.

CARTO-3. The CARTO-3 system is the third-generation platform from Biosense Webster that offers two additional features: Advanced Catheter Location Technology and Fast Anatomical Mapping (FAM). Advanced Catheter Location technology is a hybrid technology that combines magnetic location technology and current-based visualization data to provide accurate visualization of multiple catheter tips and curves on the electroanatomic map. It allows the visualization of up to five EP catheters (with and without the magnetic sensors) simultaneously with clear distinction of all electrodes. In addition to the previously noted magnetic field, CARTO-3 uses an electrical field created by two sets of patches (three on the patient's back, three on the chest). The system sends a low-intensity current at a unique frequency that is emitted by various catheter electrodes, and the strength of the current emitted by each electrode is measured at each patch; this creates a current ratio unique to each electrode's location. The magnetic technology calibrates the current-based technology and thereby minimizes distortions at the periphery of the electrical field. Visualization of catheters is confined into a 3-D virtual area called the "matrix," which can be built only by using a magnetic sensor-equipped manufacturer-specific catheter (Figs. 6.1 and 6.2).²

Mapping is performed in two steps. Initially the magnetic mapping permits precise localization of the catheter with the sensor. This is associated with the current ratio of the electrode closest to the sensor. As the catheter with the sensor moves around a chamber, multiple locations are acquired and stored by the system. The system integrates the current-based points with their respective magnetic locations, resulting in a calibrated current-based field that permits accurate visualization of other catheters and their locations. Since each electrode emits a unique frequency, individual electrode locations are distinct, even when they are close to each other. FAM is a feature that permits rapid creation of anatomical maps by movement of a sensor-based catheter throughout the cardiac chamber. Unlike point-by-point electroanatomic mapping, volume data can be collected with FAM (see Fig. 6.1).

CARTO-Merge. The CARTO-Merge Module allows for images from preacquired computed tomography (CT) angiogram or MRI volume data sets to be integrated on the electroanatomic image of the cardiac

Fig. 6.1 The CARTO Electroanatomic Mapping System. (A) The three hemispheres represent fields from three different electromagnets situated beneath the patient. The catheter tip contains an element that is sensed by these fields, and this triangulating information is used to monitor the location and orientation of the catheter tip in the heart. (B) The magnetic field emitter, mounted under the operating table, is shown in relation to six electrode patches positioned at the patient's back and chest monitor (to create an electrical field and allow current-based visualization of catheters not equipped by magnetic sensors). The electroanatomic map is shown in the middle. (C) Color-coded activation map superimposed on the virtual anatomical geometry of the right atrium (left anterior oblique view) during mapping and ablation of typical atrial flutter using the CARTO-3 electroanatomic mapping system. Three standard diagnostic catheters are visualized on the electroanatomic map: Halo catheter positioned around the tricuspid annulus (TA); decapolar catheter positioned in the coronary sinus (CS); and multielectrode PentaRay catheter positioned at the right atrial posterior wall. The PentaRay and decapolar catheters are equipped with magnetic sensors and can be used to collect electroanatomic data. Current-based data are used to enable visualization of the Halo catheter. IVC, Inferior vena cava.

coronary circulation is a concern, such an overlay of the coronary angiogram allows RF energy application without the need for repeated coronary angiography. It is important to recognize, however, that the fluoroscopy or angiographic images are not gated to the electrocardiogram (ECG) or respiratory cycle, and any shift in of the prerecorded image during the course of the study requires the acquisition of new x-ray images.³

CARTO-Sound. The CARTO-Sound Image Integration Module incorporates the electroanatomic map to a map derived from intracardiac echocardiography (ICE), and allows for 3-D reconstruction of the cardiac chambers using real-time ICE. ICE is performed using a phased-array transducer catheter incorporating a navigation sensor (SoundStar, Biosense Webster) that records individual 90-degree sector image planes of the cardiac chamber of interest, including their location and orientation, to the CARTO workspace. A 3-D volume-rendered image is created by obtaining ECG-gated ICE images of the endocardial surface of the cardiac chamber of interest (Fig. 6.4). Three-second segments of 2-D ICE images are acquired during ECG gating to the P wave during sinus rhythm and to the R wave during AF. Since ICE images are not automatically gated to respiration by the system, images used in the analysis are acquired in the late-expiration to the midexpiration phase. Following optimizing each image by adjusting frequency (5 to 10 MHz) and contrast, the chamber endocardial surfaces are identified (based on differences in the echo intensity of blood and tissue), and their contours are traced automatically, and overwritten by hand as necessary, using the CARTO-Sound software. The contour lines for the chamber of interest are drawn below the border to prevent image bloating. The software then resolves each contour into a series of discrete spatial points, with an interpoint spacing of up to 3 mm (closer spacing on curved contours or at angulations). The CARTO software interpolates these points to create models of the chamber endocardial surface in the CARTO workspace. CARTO-Sound allows for detailed real-time visualization of the cardiac chamber and of its adjacent structures, and elimination of the chamber deformity that often happens with contact mapping.^{4,5}

CARTO-Sound has been successfully utilized to facilitate AF catheter ablation by incorporating a real-time ICE volume map of the left atrium (LA) and pulmonary veins (PVs) with the electroanatomic map, either as a stand-alone tool to guide navigation and ablation or as a facilitator of CT/MRI image integration. In addition, studies have shown the

chamber created with the CARTO system and simultaneously display them within the same coordinate system (Fig. 6.3). This can be very valuable in guiding real-time catheter ablation using the detailed cardiac chamber anatomy acquired from the CT/MRI.

CARTO-Univu. The CARTO-Univu module permits overlaying of the 3-D anatomic map and catheter visualization on prerecorded x-ray images or cine loops. When proximity of the ablation target to the

Fig. 6.2 CARTO-3 Color-Coded Activation Map of Focal Atrial Tachycardia Originating From the Left Atrial Appendage (LAA). The ablation catheter is positioned at the roof of the LAA (*black arrow*). A shadow of the position of the ablation catheter at the successful ablation site is marked (*white arrow*). A multipolar Halo catheter is positioned in the right atrium around the tricuspid annulus and a decapolar catheter is positioned in the coronary sinus (CS). Shadows of the original position of each of the catheters are marked for reference. Both Halo and CS catheters are not equipped with magnetic sensors and cannot be used to collect electroanatomic data. Visualization of these catheters is enabled by current-based data and is confined into a 3-D virtual area called the “matrix,” which can be built only by using a magnetic sensor-equipped manufacturer-specific catheter. Red dots indicate radiofrequency ablation lesions. feasibility of using CARTO-Sound to define scar boundaries in the left ventricle (LV; identified on ICE imaging by both by wall thickness and motion) to facilitate substrate mapping and ablation of ischemic VT. Of note, when AF ablation is guided by 3-D ICE-derived images, ablation points fall beyond the 3-D ICE-derived surface contour more often than when guided by FAM or merged 3-D ICE-CT volume rendering.⁴

EnSite NavX Electroanatomic Mapping System

The EnSite NavX system consists of a set of three pairs of skin patches—a system reference patch, ECG electrodes, a display workstation, and a patient interface unit. The reference patch is placed on the patient's abdomen and serves as the electrical reference for the system.

The EnSite NavX combines catheter location and tracking features of the Localisa system (Medtronic, Minneapolis, MN, United States) with the ability to create an anatomical model of the cardiac chamber using only a single conventional EP catheter and skin patches. This mapping modality is based on currents across the thorax, developed as originally applied in the Localisa system. In contrast to the NavX system, Localisa does not allow the generation of 3-D geometry of the heart cavity because catheters and desired anatomical landmarks are displayed in a Cartesian frame of reference. This technology has undergone substantial additional development in the NavX iteration.²

For 3-D navigation, six electrodes (skin patches) are placed on the patient's skin to create electrical fields along three orthogonal axes (x,

Fig. 6.4 The CARTO-Sound Image Integration Module. (A) Intracardiac echocardiographic image showing the left atrium (LA) and left inferior pulmonary vein (PV) obtained using a 10 Fr phased-array transducer catheter. The endocardial surfaces of the LA and PV are traced. (B) Three-dimensional geometry of the LA is reconstructed by interpolation of points on the traced endocardial surface from multiple ICE images. (C) CARTO-3 anatomical reconstruction of the LA (posterior view). Note that the circular and ablation catheters are visualized in the left inferior PV. (D) Integration of the CARTO-Sound volume and the electroanatomic maps of the LA. LSPV, Left superior PV; RIPV, right inferior PV; RSPV, right superior PV.

y, and z). The patches are placed on both sides of the patient (x-axis), the chest and back (y-axis), and the back of the neck and inner left thigh (z-axis). Analogous to the Frank lead system, the three orthogonal electrode pairs are used to send three independent, alternating, low-power currents of 350 mA at a frequency of 5.7 kHz through the patient's chest in three orthogonal (x, y, and z) directions, with slightly different frequencies of approximately 30 kHz used for each direction, to form a 3-D transthoracic electrical field with the heart at the center. The absolute range of voltage along each axis varies from each other, depending on the volume and type of tissue subtended between each surface-electrode pair. The voltage gradient is divided by the known applied current to determine the impedance field that has equal unit magnitudes in all three axes. Each level of impedance along each axis corresponds to a specific anatomical location within the thorax. As standard catheter electrodes are maneuvered within the chambers, each catheter electrode senses the corresponding levels of impedance, derived from the measured voltage. The mixture of the 30-kHz signals, recorded from each catheter electrode, is digitally separated to measure the amplitude of each of the three frequency components. The three electrical field strengths are calculated automatically via the difference in amplitudes measured from neighboring electrode pairs with a known interelectrode distance for three or more different spatial orientations of that dipole. Timed with the current delivery, NavX calculates the x-y-z impedance coordinates at each catheter electrode by dividing each of the three amplitudes (V) by the corresponding electrical field strength (V/cm), and expresses them in millimeters to locate the catheters graphically in real time to enable nonfluoroscopic navigation. The NavX system allows real-time visualization of the position and motion of up to 128 electrodes on both ablation and standard catheters positioned elsewhere in the heart (Fig. 6.5). Importantly, the relative positions of the electrodes are

calculated by assuming that changes in the recorded field potential are only caused by changes in catheter position. Therefore changes in thoracic impedance can cause the system to "drift."²

The NavX system also allows for rapid creation of detailed models of cardiac anatomy. Sequential positioning of a catheter at multiple sites along the endocardial surface of a specific chamber establishes that chamber's geometry. The system automatically acquires points from a nominated electrode at a rate of 96 points/s. Chamber geometry is created by several thousand points. The algorithm defines the surface by using the most distant points in any given angle from the geometry center, which can be chosen by the operator or defined by the system. In addition, the operator is able to specify fixed points that represent contact points during geometry acquisition; the algorithm that calculates the surface cannot eliminate these points. In addition to mapping at specific points, there is additional interpolation, providing a smooth surface onto which activation voltages and times can be registered (see Fig. 6.5). To control for variations related to the cardiac cycle, data acquisition can be gated to any electrogram. Also, electrode positions are averaged over a few seconds to minimize the effect of cardiac motion. Respiratory compensation is collected just before mapping. The algorithm records the movement that occurs with respiration and correlates it with changes in transthoracic impedance to filter low-frequency cardiac shift associated with the breathing cycle.

After creating chamber geometry, a scaling algorithm (field scaling) is applied to compensate for variations in impedance between the heart chambers and venous structures, which can otherwise result in a distortion of the x-y-z coordinates when a "roving" catheter is maneuvered among the differing regions of impedance (Fig. 6.6). Field scaling is based on the measured interelectrode spacing for all locations within the geometry. Adjustments to the local strength of the navigation fields

are made so that the computed catheter electrode positions match the known interelectrode spacing of the catheters used to create the geometry.

The NavX system works with most manufacturers' ablation catheters, RF generators, or cryogenerators. Sites of ablation energy application can be tagged, thus facilitating the creation of lines of block with considerable accuracy by serial placement of energy applications and allowing verification of the continuity of the ablation line.

The EnSite Fusion iteration has the capability to integrate images from a preacquired CT/MRI scan on the real-time electroanatomic image the cardiac chamber created with the NavX system to facilitate anatomically based ablation procedures. To allow local adjustment of the EnSite System model, the registration module comes with Dynamic Registration. The system has the ability to mold the created geometry dynamically into the CT/MRI image (see later discussion).

The EnSite Precision iteration adds magnetic navigation capability. Magnetic points are collected with several new magnet-enabled catheters. Magnetic-field stability reduces the effects of "impedance drift," corrects impedance distortion, and helps optimize catheter navigation and creation of a precise, accurate geometry model.

Rhythmia Electroanatomic Mapping System

Rhythmia is a novel 3-D electroanatomic mapping platform that is paired to a mini-basket array catheter with 64 mini-electrodes (Orion, Boston Scientific) and is capable of generating ultra-high-density electroanatomic maps. This system uses a hybrid location technology that combines impedance and magnetic location. The magnetic field is generated by a localization generator positioned under the patient's table and is capable of locating catheters with magnetic sensors. The impedance location technology is used to track catheters that are not equipped with a magnetic sensor. The system then maps the impedance field measurements to the magnetic location coordinates and creates

Fig. 6.7 The Orion Mini-Basket Catheter. The 8-F bidirectional mini-basket catheter is 27 mm long from the catheter shaft to the distal tip of the basket. It consists of 8 splines, each with 8 electrodes. The nominal diameter of the basket is 18 mm when measured at its equator. (From Anter E, Tschabrunn CM, Contreras-Valdes FM, Li J, Josephson ME. Pulmonary vein isolation using the Rhythmia mapping system: verification of intracardiac signals using the Orion mini-basket catheter. *Heart Rhythm*. 2015;12:1927–1934.)

an impedance field map. This map is used to enhance the accuracy of the impedance location.^{6,7}

Orion is an 8.5 Fr bidirectional deflectable catheter with a mini-basket electrode array containing eight splines, each spline containing eight small electrodes (Fig. 6.7). The surface area of each electrode is 0.4 mm², and the interelectrode spacing is 2.5 mm (measured from center to center). The basket can be deployed into a spherical configuration through mechanical flexion of the splines to varying diameter (minimum 3 mm, nominal 18 mm, maximum 22 mm, when measured at its equator). The location of each electrode is determined using a combination of magnetic sensor located at the tip of the catheter and impedance sensing at each of the electrodes. A flushing mechanism is present at the catheter tip to prevent thrombus formation. Other catheters are tracked by an impedance-based system.^{6–9}

Two data acquisition modes are available with the Orion catheter: continuous and manual. In the continuous data acquisition mode, operator-defined criteria for accepting cardiac beats are applied for automated map construction during uninterrupted movement of the catheter, without immediate input from the operator. The electrograms from collected beats are automatically annotated by the system. In the manual data acquisition mode, the operator collects data in an “area-by-area” manner, and manually accepts and annotates selected points.

During continuous, automated data acquisition, points are accepted only if they meet user predefined acceptance criteria such as cycle length (CL) stability, stable timing difference between two reference electrodes, respiration gating (the respiratory cycle is tracked by measuring impedance change across the chest), stable catheter location, stability of catheter signal compared with adjacent points, and morphology matching. The automated algorithms filter out points with discrepancy in comparison to those of close proximity. Far-field components are reduced by combining unipolar and bipolar electrograms.

The setup for the mapping window is automatic. The system calculates the mean CL of the rhythm over 10 seconds and consequently sets 100% of the CL equally before and after the timing reference electrode (usually one of the coronary sinus [CS] electrograms, or the QRS interval of one of the surface ECG leads for ventricular rhythms). For annotation of the local activation time of each acquired electrogram, the system combines unipolar (maximum negative dV/dt) and bipolar (maximum amplitude) electrogram. For electrograms with multiple potentials, the system selects the potential that best matches the timing of electrograms in the surrounding area.^{6–8} The very small size of the

electrodes on the Orion catheter minimizes far-field signals and background noise, and allows accurate detection of very small amplitude signals.^{10,11}

The anatomical shell is gradually constructed with every accepted beat based on the location of the outermost electrodes of the basket catheter. Inclusion or exclusion of electrograms into the group of surface electrograms is based on the distance from the surface geometry (1 to 5 mm), which can be set by the operator. The system will automatically delete inner electrogram points as more signals are recorded from a spatially outside location.^{6–8}

All electrograms are stored for later review. Maps can be edited by the operator after data acquisition is complete. The software allows for visualization of the electrogram associated with each anatomic point, facilitating re-annotation or removal of inaccurate data.⁷ By selecting individual electrograms with a virtual roving probe, it is possible to determine and mark a region of interest (e.g., His bundle [HB] region). In addition, a cutout of anatomical structures such as the tricuspid annulus can be performed based on the corresponding electrograms in review mode (Fig. 6.8).^{12,13}

Electroanatomic Activation Mapping

Anatomical Reference

Once the mapping catheter (or any electroanatomically tracked electrode) is placed inside the heart, its location can be determined in relation to a fixed anatomical reference. This reference catheter is positioned inside the heart or on the body surface, and its location must remain stable throughout the procedure to prevent distortion of the electroanatomic map. The movement of the mapping catheter is then tracked relative to the position of this reference. An intracardiac reference catheter has the advantage of moving with the patient's body and with the heart during the phases of respiration. However, the intracardiac reference catheter can change its position during the course of the procedure, especially during manipulation of the other catheters.

In the CARTO mapping system, locations of magnetically enabled catheters are displayed in relation to the fixed magnetic field sensors placed under the patient. The CARTO system continuously calculates the position of the mapping catheter in relation to this array of sensors, thus solving the problem of any possible motion artifacts. The movement of the ablation catheter is then tracked relative to the position of this reference. Slight movement of the patient relative to the location reference pad may distort the map; significant patient movement or dislocation of the location pad can lead to uncorrectable map shifts.

In the NavX system, the 3-D localization of all EP catheters is based on an impedance gradient-calculation system in relation to a reference electrode placed on the patient's body or inside the heart (e.g., CS catheter). Since the reference electrodes and catheters are placed either on the patient's skin or in the patient's cardiac chambers, they move simultaneously with the patient, preventing map shifts and rendering the NavX largely insensitive to potential patient movements.² The Rhythmia system also uses an anatomical sensor attached to patient's back.

The Rhythmia mapping system uses a hybrid location technology that combines impedance location with magnetic location technology and uses two location references, one for each localization technology. The magnetic technology uses a location reference attached to the patient's back, while the impedance technology uses a stationary intracardiac electrode (e.g., a CS electrode) selected by the user.

Electrical Reference

The electrical reference is the fiducial marker on which the entire mapping procedure is based. The timing of the fiducial point is used to determine the activation timing in the mapping catheter in relation to the acquired points and to ensure collection of data during the same part of the

Fig. 6.8 Rhythmia Color-Coded Activation Map of Typical Counterclockwise Atrial Flutter (AFL). Three-dimensional electroanatomic activation map of the right atrium in the right anterior oblique (*left*) and left anterior oblique (*right*) views constructed during counterclockwise typical AFL. During tachycardia, the depolarization wavefront travels counterclockwise around the tricuspid annulus (TA), as indicated by a continuous progression of colors (from red to purple) with close proximity of earliest and latest local activation. The mini-basket (Orion) catheter is visualized on the map. CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava.

cardiac cycle. It is therefore vital to the performance of the system. All the local activation timing information recorded by the mapping catheter at different anatomical locations during mapping (displayed on the completed 3-D map) is relative to this fiducial point, with the acquisition gated so that each point is acquired during the same part of the cardiac electrical signal. It is important that the rhythm being mapped is monomorphic and the fiducial point is reproducible at each sampled site.

The fiducial point is defined by the user by assigning a reference channel and an annotation criterion. The system has a great deal of flexibility in terms of choosing the reference electrogram and gating locations. Any surface ECG lead or intracardiac electrogram in bipolar or unipolar mode can serve as a reference electrogram. For the purpose of stability when intracardiac electrograms are selected, CS electrograms are usually chosen for mapping supraventricular rhythms, and a right ventricle (RV) electrode or a surface ECG lead is commonly chosen as the electrical reference during mapping ventricular rhythms. Care must be taken to ensure the reference electrogram is distinct and stable, and that automatic sensing of the reference is reproducible and is not subject to oversensing in the case of annular electrograms (e.g., oversensing of a ventricular electrogram on the CS reference electrode during mapping an atrial rhythm). Any component of the reference electrogram may be chosen for a timing reference, including maximum (peak positive) deflection, minimum (peak negative) deflection, maximum upstroke (dV/dt), or maximum downslope.¹

Window of Interest

Defining an electrical window of interest is a crucial aspect in ensuring the accuracy of the initial map coordinates. The window of interest is defined as the time interval relative to the fiducial point during which the local activation time is determined (Fig. 6.9). Within this window, activation is considered early or late relative to the reference. Timing and voltage of electrograms falling outside this window are excluded from the map and cannot be tagged without altering the window. The total length of the window of interest should not exceed the tachycardia cycle length (TCL; generally 10 or 20 milliseconds less than the TCL). The boundaries are set relative to the reference electrogram. Thus the

window is defined by two intervals—one extending before the reference electrogram and the other after it. For focal tachycardias, the window of interest is usually selected so that it starts about 50 milliseconds before the onset of the tachycardia complex on the surface ECG (P wave or QRS), regardless of the timing of the electrical reference. For macroreentrant tachycardias, the sensing window should approximate the TCL, and designating activation times in a circuit as early or late is arbitrary. If the activation window spans more than one tachycardia cycle, the resulting map can be ambiguous, lack coherency, and give rise to a spurious pattern of adjacent regions of early and late activation (Figs. 6.9 and 6.10). In theory, a shift in the window or electrical reference would not change a macroreentrant circuit but only result in a phase shift of the map (Fig. 6.11).¹

Local Activation Time

Once the reference electrogram, anatomical reference, and window of interest have been chosen, the mapping catheter is moved from point to point along the endocardial surface of the cardiac chamber being mapped. These points can be acquired in a unipolar or bipolar configuration. These electrograms are analyzed using the principles of activation mapping discussed in Chapter 5. The local activation time at each sampled site is calculated as the time interval between the fiducial point on the reference electrogram and the corresponding local activation determined from the unipolar or bipolar local electrogram recorded from that site.

In general, the local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed reference electrogram. For bipolar electrograms, the initial peak of a filtered (30 to 300 Hz) bipolar signal coincides with depolarization beneath the recording electrode and appears to correlate most consistently with local activation time, corresponding to the maximal negative dV/dt of the unipolar recording. However, in the setting of complex multicomponent or fractionated bipolar electrograms, the determination of local activation time becomes challenging, and the decision about which activation time is most appropriate needs to be made in the context of the particular rhythm being mapped. Therefore, during mapping procedures, the onset (rather than the peak or nadir) of a

A. Correct window width

B. Window too wide

C. Window too narrow

Fig. 6.9 Influence of Window of Interest on Activation Mapping. CARTO-3 activation map of a macro-reentrant left atrial tachycardia is shown (anterior-cranial view). In (A) the correct window of interest width was chosen encompassing one complete cardiac cycle. A mid-diastolic potential (*red arrow*) is recorded from the top of the left atrium, with its timing at the left portion of the window (*darker vertical panel*), giving rise to an activation map at left with direction of propagation as indicated by the white arrow. In (B) the window of interest is too wide, including portions of two cardiac cycles. It is possible for the activation at this same site to be assigned as indicated by the red arrow, yielding a completely different activation map at left, seeming to show splitting of wavefronts going around the right pulmonary veins (PVs). In (C) the window is too narrow, and while no actual electrogram occurs within the window, the system is obligated to take an activation time (noise, at *red arrow*). This again yields a very different activation map as shown at left. LSPV, Left superior PV; LIPV, left inferior PV; RSPV, right superior PV; RIPV, right inferior PV.

Fig. 6.11 Influence of the Electrical Reference on Activation Mapping. CARTO-3 activation map of the right atrium (left anterior oblique view) constructed during typical atrial flutter (cycle length [CL], 310 milliseconds) with “counterclockwise” rotation around the tricuspid annulus (TA). (A) The distal bipole of a Halo catheter (positioned at the lateral aspect of the TA, indicated by *yellow star*) was selected as the electrical reference (fiducial point) of the activation map. Note that the early-meets-late zone is located at the septal aspect of the right atrium. The window of interest was set at 300 milliseconds (150 milliseconds before to 150 milliseconds after the timing of the electrical reference). (B) The proximal bipole of the coronary sinus (CS) catheter (positioned at the CS ostium, indicated by *yellow star*) was selected as the electrical reference for activation mapping of the same tachycardia. Again, the window of interest was set at 150 milliseconds before to 150 milliseconds after the timing of the electrical reference. Now, the early-meets-late zone is located at the lateral aspect of the RA. In both maps, there is continuous progression of colors (from *red* to *purple*) with close proximity of earliest and latest local activation (*red* meeting *purple*), consistent with counterclockwise peritricuspid reentry. The change in the electrical reference did not cause a change a macro-reentrant circuit but only resulted in a phase shift of the map. Note that the early-meets-late zone in both maps does not localize the ablation target (which is the cavotricuspid isthmus in these cases); rather, it is merely a function of where the offset and onset of the window of interest are defined relative to the timing of the selected electrical reference. IVC, Inferior vena cava; SVC, superior vena cava.

high frequency component of the local bipolar electrogram often is used because it is easier to determine reproducibly, especially when measuring heavily fractionated, low-amplitude local electrograms. The onset of the bipolar electrogram likely precedes the maximal $-dV/dt$ in unipolar electrogram by 15 to 30 milliseconds.¹⁴

For filtered and unfiltered unipolar electrograms, the maximum negative slope (i.e., maximum change in potential, dV/dt_{\max}) of the signal coincides best with the arrival of the depolarization wavefront directly beneath the electrode.^{14–16}

Contemporary mapping systems offer automatic data acquisition and timing annotation of accepted points. Using these automated algorithms, timing of local activation is annotated at the point of maximum amplitude of the bipolar signal or the maximum negative dV/dt of the unipolar signal. For electrograms with multiple potentials, the system selects the potential that best matches the timing of electrograms in the surrounding area. When automated timing annotation is used, it is important to utilize the same parameters for the timing of local activation when additional points are acquired manually or during the editing of automatically acquired data.

Data Acquisition

Following selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest, the mapping catheter is positioned in the cardiac chamber of interest.

The CARTO and Rhythmia systems require the use of proprietary catheters with a location sensor to collect mapping data. In contrast, NavX-guided procedures are performed using the same catheter setup as conventional approaches. Any electrode can be used to gather data, create static isochronal and voltage maps, and perform ablation procedures. Standard EP catheters of choice are introduced into the heart; up to 128 electrodes can be viewed simultaneously. The NavX system can locate the position of the catheters from the moment that they are inserted in the vein. Therefore all catheters can be navigated to the heart under guidance of the EnSite NavX system, and the use of fluoroscopy can be minimized for preliminary catheter positioning. However, interrupted fluoroscopy must be used repeatedly when an obstacle to catheter advancement is encountered. Once in the heart, one intracardiac catheter is used as a reference for geometry reconstruction. A shadow (to record original position) is placed over this catheter to recognize displacement during the procedure, in which case the catheter can be returned easily to its original location under the guidance of NavX. A shadow can also be displayed on each of the other catheters to record that catheter's exact spatial position at some particular time (e.g., where PV potentials are best seen).

The mapping catheter is initially positioned (using fluoroscopy) at known anatomical points that serve as landmarks in the chamber of interest for the electroanatomic map. For example, to map the right atrium (RA), points such as the superior vena cava (SVC), inferior vena

cava (IVC), HB, tricuspid annulus, and CS os are marked. The catheter is then advanced slowly around the chamber walls to sample multiple points along the endocardium, thus sequentially acquiring the location of its tip together with the local electrogram.

Points are selected only when the catheter is in stable contact with the wall. The system continuously monitors the quality of catheter-tissue contact and local activation time stability to ensure the validity and reproducibility of each local measurement. The stability of the catheter and contact is evaluated at every site by examining the following: (1) local activation time stability, defined as a difference between the local activation calculated from two consecutive beats of less than 2 milliseconds; (2) location stability, defined as a distance between two consecutive gated locations of less than 2 mm; (3) morphological super-impositioning of the intracardiac electrogram recorded on two consecutive beats; and (4) CL stability, defined as the difference between the CL of the last beat and the median CL during the procedure. Furthermore, contact force measurement at the tip of the mapping electrode (when available) can help optimize electrode-tissue contact and improve mapping accuracy.

Contemporary mapping systems enable automated data acquisition from the designated mapping catheter. The algorithm automatically accepts and annotates activation times for points that fulfill an operator-defined set of acceptance criteria. Beats are included in the map based on CL stability, relative timing of reference electrograms, electrode location stability, and respiratory gating, among other optional criteria. These algorithms help streamline the mapping and validation process and reduce overall mapping and manual annotation time.

Because respiratory excursions can cause significant shifts in apparent catheter location, respiratory compensation is collected just before mapping to filter low-frequency cardiac shift associated with the breathing cycle. The current iteration of the CARTO mapping system allows for automatic gating to the respiratory cycle.¹

Each selected point is tagged on the 3-D map. Lines of block (manifest as double potentials) are tagged for easy identification because they can serve as boundaries for the subsequent design of ablation strategies. Electrically silent areas (defined as having an endocardial potential amplitude less than 0.05 mV [the baseline noise in the mapping system], and the absence of capture at 20 mA) and surgically related scars are tagged as “scar” and therefore appear in gray on the 3-D maps and are not assigned an activation time (see Figs. 14.1 and 14.2). The map can also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia.¹

Sampling the location of the catheter together with the local electrogram is performed from multiple endocardial sites. Catheters other than the ablation catheter, such as the multipolar Lasso or Penta-Ray, can further enhance the collection of points, increase the mapping speed, and improve map resolution. The points sampled are connected by lines to form several adjoining triangles in a global model of the chamber. Next, gated electrograms are used to create an activation map, which is superimposed on the anatomical model. The acquired local activation times are then color-coded and superimposed on the anatomical map, with red indicating early-activated sites, blue and purple indicating late-activated areas, and yellow and green indicating intermediate activation times (see Figs. 6.5 and 6.11). Between these points, the mapping systems assign an activation time over the area around each acquired point, and the adjoining triangles are colored with these interpolated values. The size of this area is determined by setting the triangle “fill threshold” or “interpolation threshold,” which is adjustable. If the points are spaced widely apart (beyond the fill threshold), no interpolation is done. As each new site is acquired, the reconstruction is updated in real time to create a 3-D chamber geometry color progressively encoded with activation time.¹

Sampling an adequate number of homogeneously distributed points is necessary. If inadequate numbers of points are taken and the fill threshold allows interpolation over a large area, the colors assigned to the poorly mapped areas will not be representative of the actual conduction pattern and activation timing. Thus bystander sites can be mistakenly identified as part of a reentrant circuit, and lines of conduction block can be missed. In addition, low-resolution mapping can obscure other interesting phenomena, such as the second loop of a dual-loop tachycardia. Some arrhythmias, such as complex reentrant circuits, require more than 80 to 100 points to obtain adequate resolution. Other tachycardias can be mapped with fewer points, including focal tachycardias and some less complex reentrant arrhythmias, such as isthmus-dependent AFL. The use of multielectrode mapping catheters can improve map resolution and expedite the mapping process.¹

It is also important to identify areas of scar or central obstacles to conduction; failure to do so can confuse an electroanatomic map because interpolation of activation through areas of conduction block can give the appearance of wavefront propagation through, rather than around, those obstacles. This occurrence precludes identification of a critical isthmus in reentrant arrhythmias to target for ablation. A line of conduction block can be inferred if there are adjacent regions with wavefront propagation in opposite directions separated by a line of double potentials or dense isochrones.

The electroanatomic model, which can be viewed in a single view or in multiple views simultaneously and freely rotated in any direction, forms a reliable road map for navigation of the ablation catheter. Any portion of the chamber can be seen in relation to the catheter tip in real time, and points of interest can easily be revisited even without fluoroscopy. The electroanatomic maps can be presented in two or three dimensions as activation, isochronal, propagation, or voltage maps.

Activation Map

During mapping, the electrogram obtained at a given site is stored and the activation time catalogued as compared with the designated reference electrogram. The accrued points in the map are assigned to an isochronal color scale based on their respective activation times. The activation maps display the local activation time, color-coded and overlaid on the reconstructed 3-D geometry (see Figs. 11.21 and 12.14). Each color shift represents a temporal fraction of the entire TCL. Activation mapping is performed to define the activation sequence. A reasonable number of points homogeneously distributed in the chamber of interest must be recorded. The selected points of local activation time are color-coded.

The electroanatomic maps of focal tachycardias demonstrate radial spreading of activation, from the earliest local activation site in all directions, and in these cases, activation time is markedly shorter than TCL (Fig. 6.2). In contrast, a continuous progression of colors around the mapped chamber, with close proximity of earliest and latest local activation (“early-meets-late” zone), suggests the presence of a macroreentrant tachycardia (see Fig. 6.11). Importantly, the early-meets-late zone should not be used as an indicator of the location of the critical isthmus of the macroreentrant circuit (which is the usual ablation target). Rather, it is merely a function of where the offset and onset of the window of interest are defined relative to the timing of the selected reference electrogram. As noted previously, the early-meets-late zone can shift in location and timing in response to shifts in the window of interest or electrical reference (see Figs. 6.8 and 6.11).¹

It is also important to recognize that a focal tachycardia can produce an electroanatomic activation map that mimics reentry when anatomical or functional barriers to conduction close to the site of origin of the tachycardia (such as anisotropic conduction, scars, incisions, or prior ablation lines) cause the delay of wavefront propagation to span the

Fig. 6.12 Focal Versus Macroreentrant Atrial Tachycardia (AT) in a Patient With Prior Cavotricuspid Isthmus Ablation. A right atrial electroanatomic map during AT (tachycardia cycle length [TCL] 390 milliseconds) is shown. At left, the activation pattern (arrows) suggests typical counterclockwise atrial flutter; mapped sites account for 384 milliseconds (98% of TCL). Overdrive pacing had suggested a focal automatic process; additional mapping showed a focal site at the coronary sinus (CS) ostium (right panel, asterisk) where ablation terminated AT. A revised pattern of activation shows propagation in both directions from the focus. IVC, Inferior vena cava; SVC, superior vena cava.

entire TCL and arrive late to sites close to the focus of the tachycardia. For example, a focal AT originating from the coronary sinus ostium (CS os) in a patient with prior cavotricuspid isthmus (CTI) ablation can produce an electroanatomic map mimicking that of peritricuspid macroreentry (counterclockwise typical AFL; Fig. 6.12). When the “early-meets-late zone” is observed in an activation map that does not span the entire TCL, inadequate mapping should be suspected and more detailed mapping should be performed before concluding macroreentry as the mechanism of the tachycardia.

On the other hand, a macroreentrant tachycardia can produce an electroanatomic activation map that mimics a focal mechanism. If an insufficient number of activation points is obtained, it may be falsely concluded through the interpolation of activation times that the wavefront propagates from a focal source (see Fig. 13.11).¹⁷ This is frequently encountered when the macroreentrant tachycardia originates from the chamber contralateral to the one being mapped. In the latter situation, the activation map will localize the site of the earliest local activation to the earliest breakthrough of conduction into the chamber being mapped. Notably this breakthrough location, although showing the earliest recorded activation timing relative to the intracardiac electrical reference, may not be presystolic (as compared with the onset of the P wave or QRS on the surface ECG) and, hence, cannot be the site of origin of a focal tachycardia. This provides an additional clue to help interpret the activation map and should prompt more detailed mapping. Similarly, a focal pattern can be observed during endocardial mapping when significant parts of the macroreentry circuits are located intramurally or epicardially.

Isochronal Map

The electroanatomic mapping system can generate isochrones of electrical activity as color-coded static maps. The isochronal map depicts

all the points with an activation time within a specific range (e.g., 10 milliseconds) with the same color. Depending on conduction velocity, each color layer is of variable width; isochrones are narrow in areas of slow conduction and broad in areas of fast conduction. Displaying information as an isochronal map helps demonstrate the direction of wavefront propagation, which is perpendicular to the isochronal lines, along the vector of the color changes. Furthermore, isochronal crowding (i.e., multiple colors evident over a small distance) indicating a conduction velocity of 0.033 cm/msec (slower than 0.05 cm/msec) is considered a zone of slow conduction, whereas a collision of two wavefronts traveling in different directions separated temporally by 50 milliseconds is defined as a region of local block. Spontaneous zones of block or slow conduction (less than 0.033 cm/msec) may have a major role in the stabilization of certain arrhythmias.

Propagation Map

Activation mapping data can be displayed in a color-coded animated dynamic map of activation wavefront (propagation map; see Figs. 11.21 and 12.13). Propagation of electrical activation is visualized superimposed on the 3-D anatomical reconstruction of the cardiac chamber in relation to the anatomical landmarks and barriers. Analysis of the propagation map can allow estimation of the conduction velocity along the reentrant circuit and identification of areas of slow conduction.

EnSite Precision enables the visualization of propagation of the activation wavefront over voltage maps, which better illustrate activation patterns in relation to regions of electrical scar (Fig. 6.13).

Entrainment Map

A graphical representation of entrainment mapping can be constructed by plotting values of the differences between the postpacing intervals (PPIs) and the TCLs (PPI–TCL) on the electroanatomic mapping system

Fig. 6.13 Propagation Map of Typical Atrial Flutter (AFL). Activation and voltage maps of the right atrium are acquired during typical counterclockwise AFL using the EnSite Precision mapping system. Voltage maps are shown in the left anterior oblique projection. Red color corresponds to endocardial atrial bipolar potentials with an amplitude of ≤ 0.1 mV; purple color corresponds to electrogram amplitude of ≥ 1 mV. (A to D) Propagation of the activation wavefront is visualized over the voltage map as bright green dots (“sparkles”) traveling in a counterclockwise direction around the tricuspid annulus (TA), as indicated by the white arrows. CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava.

Fig. 6.14 Electroanatomic Color-Coded Entrainment Mapping. Left atrial (LA) electroanatomic color-coded entrainment map in a patient with atrial tachycardia following pulmonary vein isolation for treatment of atrial fibrillation. The LA is shown in various attitudes as indicated. The colors represent the difference between the postpacing interval (PPI) at each site following entrainment pacing and the tachycardia cycle length (TCL): the less the difference, the closer to the circuit. In the top row, red and orange areas have minimal difference between the PPI and TCL (i.e., in or near circuit), while purple areas have large differences (i.e., remote from circuit). Bottom row shows the same data with the timing scale set such that 0 to 30 milliseconds is red (i.e., in peri-right pulmonary veins circuit). Note that not all areas that are in the circuit are reasonable ablation target areas. MA, Mitral annulus; RIPV, right inferior pulmonary veins; RSPV, right superior pulmonary veins.

to generate color-coded 3-D entrainment maps (Fig. 6.14). This approach can potentially help accurately determine and visualize the 3-D location of the entire reentrant circuit, even though the area of slow conduction of the tachycardia is not specified. Because none of the electroanatomic mapping systems contain an algorithm for color-coding of entrainment

information, the modus for activation mapping is altered manually. At each 3-D location of the catheter tip stored on the electroanatomic mapping system, entrainment stimulation is performed, and the difference between PPI and TCL is calculated and associated with that site on the electroanatomic mapping system (as if it were an “activation

time”). For that, the local electrogram stored at the 3-D location is completely disregarded. The annotation marker is manually moved into a position where the numeric timing information equals the entrainment information (PPI–TCL). That timing information then is displayed in a color-coded fashion as if it were activation time, but instead it represents information on the length of the entrainment return cycle. With the color range, red represents points closest to the reentrant circuit (i.e., sites with smaller PPI–TCL differences, approaching 0, signifying their inclusion in the reentrant circuit) and purple represents points far away from the circuit (i.e., sites with the largest PPI–TCL differences).

Color-coded 3-D entrainment mapping allows determination of the full active reentrant circuit (vs. passively activated regions of the chamber) and the obstacle around which the tachycardia is circulating, and it provides very useful information on the location of potential ablation sites (see Fig. 6.14). However, ablation will not terminate reentry at all these sites. (Just as, although the circuit in orthodromic supraventricular tachycardia includes the ventricle, ablation at one or two sites in that ventricle will not eliminate reentry.) The final choice is determined by the location of anatomical barriers and width of putative isthmuses, so that strategic ablation lines, mainly connecting anatomical barriers, can be applied to transect the circuit and treat the arrhythmia.

Limitations of Electroanatomic Activation Mapping

Although 3-D mapping systems with image integration have been widely adopted for ablation procedures, many of their theoretical benefits remain to be proven. Therefore these systems should remain just one type among the tools facilitating complex catheter ablation procedures and should not distract the electrophysiologist from established EP principles and endpoints.¹⁸

The sequential data acquisition required for map creation remains very time-consuming because the process of creation of an electroanatomic map requires tagging many points, depending on the spatial details needed to analyze a given arrhythmia. Because the acquired data are not coherent in time, multiple beats are required, and stable, sustained, or frequently repetitive arrhythmia is usually needed for creation of the activation map. Given that these points do not provide real-time, constantly updated information, more time may be needed for making new maps to see a current endocardial activation sequence, detect a change in arrhythmia, or fully visualize multiple tachycardias. In addition, rapidly changing or transient arrhythmias are not easily recorded and may be mapped only if significant substrate abnormalities are present. For macroreentrant tachycardias, variation of the TCL by more than 10% can prevent complete understanding of a circuit, and it decreases the confidence in the electroanatomic activation map. Single premature ventricular complexes (PVCs) or premature atrial complexes (PACs) or nonsustained events may be mapped, although at the expense of an appreciable amount of time. The use of multielectrode catheters for data acquisition helps address many of these issues.

One difficulty with current methods is that incorrect assignment of activation for a few electrograms can invalidate the entire activation map, and manual adjustment is often required to achieve the optimal representation. This is the major drawback of mapping with multipolar electrode catheters; although data from a large number of sites can be acquired quickly, unless all electrograms are adjudicated to ensure correct designation of activation time by the mapping system, the map may be very misleading. In addition, data interpolation between mapped points is used to improve the quality of the display; however, areas of unmapped myocardium are then assigned simple estimates of timing and voltage information that may not be accurate.

If highly fractionated and wide potentials are present, it can be difficult to assign an activation time. In some macroreentrant circuits,

much of the TCL is occupied by fractionated low-amplitude potentials. Furthermore, the assignment of a single time value to a multicomponent electrogram does not represent the quality of the electrogram and dismisses important information about the potential role of the recorded potential in the arrhythmia circuit. The subjective selection of an individual local potential within a multicomponent electrogram can drastically alter a propagation map. If these potentials are dismissed or assigned relatively late activation times, a macroreentrant tachycardia may mimic a focal arrhythmia, and it will appear as if substantially less than 90% of the TCL is mapped.

Electroanatomic Voltage Mapping

Voltage mapping is performed to delineate the region of electrical scar that can harbor the arrhythmogenic substrate or can potentially serve as a boundary for the subsequent design of ablation strategies. This can be of significant value in the setting of unstable or unsustainable tachycardias, especially scar-related VT. Substrate mapping helps identify the VT substrate and facilitates ablation of multiple VTs, pleomorphic VTs, and VTs that are unmappable because of hemodynamic instability or poor inducibility. Substrate mapping is also of value even in well-tolerated VTs because it can help focus activation and entrainment mapping efforts on a small region harboring the VT substrate, and therefore help minimize the duration during which the patient is actually in VT. In addition, superimposition of the voltage map on the activation map can help focus auditing of the activation map to areas where low amplitude potentials are recorded.

Bipolar voltage mapping has been correlated with dense scar defined by histopathology and cardiac MRI. Electrical scar is defined by low amplitude of local electrograms and tissue inexcitability during high-output pacing. Although the true range of normal electrogram amplitude is often difficult to define, endocardial ventricular bipolar electrogram amplitude less than 1.5 mV has been accepted as an abnormally low voltage, with a cutoff of 0.5 mV as the signal amplitude that best defines the anatomical region of dense scar (Table 6.1). A pacing threshold greater than 10 mA has been used to define inexcitable scar, provided electrode-tissue contact is adequate.¹⁹ For the atrium, endocardial bipolar potentials with an amplitude of 0.5 mV or less are typically considered abnormal and termed low voltage areas (eFig. 6.1). Silent areas (scars) are defined as having an atrial bipolar potential amplitude of less than 0.05 mV and the absence of atrial capture at 20 mA.^{20–24}

A more rigid voltage cutoff criterion is used when analyzing bipolar signals on the ventricular epicardium to limit the influence of epicardial fat and coronary vasculature (see Table 6.1). As epicardial fat overlying normal myocardium insulates the underlying tissue, attenuated low-amplitude signals can be mistaken for abnormal myocardial tissue. Normal epicardial electrogram amplitude is defined as greater than 1.0 mV. Dense scar is defined as confluent areas with bipolar electrogram amplitude less than 0.5 mV, and border zone in regions with bipolar

TABLE 6.1 Voltage Criteria to Define Abnormal Myocardial Substrate

Electrogram Amplitude	Low Voltage	Dense Scar
RV and LV endocardial bipolar	<1.5 mV	<0.5 mV
RV and LV epicardial bipolar	<1.0 mV	<0.5 mV
LV endocardial unipolar	<8.3 mV	<7.0 mV
RV endocardial unipolar	<5.5 mV	<3.5 mV
RA and LA endocardial bipolar	<0.5 mV	<0.05 mV

LA, Left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

eFig. 6.1 Rhythmia Voltage Map of the Left Atrium (LA). A postero-anterior view of the LA is shown. The patient had prior catheter ablation for atrial fibrillation. Endocardial atrial bipolar potentials with an amplitude of ≥ 0.5 mV are considered normal (*purple color*). Silent areas (scars) are defined as having an atrial bipolar potential amplitude of less than 0.05 mV (*red color*). Gray color indicates electrogram amplitudes below the threshold of detection by the mapping system. Note the low voltage zones in the posterior LA wall and pulmonary vein (PV) regions consequent to prior ablation. LAA, Left atrial appendage; LIPV, left inferior PV; LSPV, left superior PV; RIPV, right inferior PV; RSPV, right superior PV.

electrogram amplitude between 0.5 and 1.0 mV. Because epicardial fat may decrease signal amplitude, low-voltage areas during epicardial mapping should also show abnormal electrogram configuration.^{19,21,22}

A limitation of bipolar recordings is that they have a limited field of view such that the amplitude of the bipolar electrogram is primarily driven by local tissue activity, while far-field activity is subtracted out. Therefore, although voltage properties of the endocardium are well-represented in the bipolar signal, intramural or epicardial scar that can potentially harbor the arrhythmogenic substrate can be missed by purely endocardial bipolar voltage mapping. In contrast, unipolar electrograms reflect the voltage difference between the exploring electrode in contact with myocardium and a second electrode that is distant from the heart (usually Wilson's central terminal). Thus the unipolar electrode has a wide field of view, and unipolar electrogram amplitude primarily represents more remote, far-field tissue depolarization.²² Therefore unipolar voltage mapping has recently been proposed to improve myocardial sensing with a wider field of view to detect the presence of midmyocardial and epicardial scar. A voltage cutoff of 8.3 mV is used to distinguish normal from abnormal LV unipolar endocardial electrogram amplitude (eFig. 6.2).¹⁹ A lower cutoff value of less than 5.5 mV defined normal unipolar voltage for the thinner free wall of the RV (see Fig. 25.4).^{21,25–27}

Electroanatomic voltage mapping can be performed during sinus, paced, or any other rhythm. The voltage map displays the peak-to-peak amplitude of the electrogram within the sampling time window at each site and is measured automatically by the mapping system. This value is color-coded and superimposed on the anatomical model (see eFig. 6.2). The gain on the 3-D color display allows the user to concentrate on a narrow or wide range of potentials. By diminishing the color scale, larger amplitude signals are eliminated.

Embedded within or between areas of dense fibrosis, isolated bundles of viable myocardium (called *conducting channels*) can potentially form protected the diastolic isthmuses necessary to support the arrhythmia circuit. Conduction through these bundles is typically slow and anisotropic, resulting in low-amplitude, multipotential, fractionated bipolar electrograms. Abnormal low-voltage electrograms can be recorded throughout extensive areas of scar that are not sufficiently specific for the components of the reentrant circuit. Thus the identification of the conducting channels within the low voltage zones helps refine the area that potentially supports the tachycardia circuit. Conducting channels can be identified on the electroanatomic voltage map as corridors of voltage preservation (voltage channels) within denser regions of scar, or as corridors between a dense scar and a valvular annulus. Careful step-by-step manual adjustment of voltage upper and lower limits on the color-coded electroanatomic voltage map (scar thresholding) can help maximize the color contrast between adjacent myocardium with different electrogram voltage levels within the 0.5-mV scar and thus unmask channels of viable myocardium within a dense scar (see eFig. 22.14 and Fig. 22.28).^{3,26}

Pacing provides complementary information to electrogram amplitude; only 2% of sites with amplitude more than 0.5 mV have a pacing threshold more than 10 mA, whereas a substantial number of very low amplitude sites have high pacing thresholds, and many sites in reentry circuit isthmuses have very low amplitudes. A dense scar is defined by the lack of electrical excitability during high-output pacing.¹⁹

Factors Influencing Voltage Mapping Resolution

Bipolar electrogram amplitude is influenced by multiple variables that can affect the accuracy and resolution of the voltage map. These include the electrode size, interelectrode distance, conduction velocity between the bipolar electrodes, vector of activation, and the angle at which the electrode engages the tissue, and signal filtering, among others.^{28–30}

Electrode size. The resolution of voltage mapping is influenced electrode size and interelectrode spacing. The spatial resolution of the standard mapping catheter is limited due to the large electrode surface area and wide interelectrode spacing. These catheters record signals produced by relatively large tissue mass and, hence, are more likely to exhibit larger bipolar electrogram amplitudes. Furthermore, low-amplitude signals produced by smaller mass of viable tissue can be lost when recorded with large electrodes. Therefore, while voltage mapping likely identifies large unexcitable areas of scar, small strands of fibrosis, which could harbor the arrhythmogenic substrate, may escape detection amidst the background of high-amplitude far-field signals. Similarly, small strands of surviving myocardium within an area of dense scar may not be detected during voltage mapping.

Smaller electrodes with closer interelectrode spacing record signals from smaller tissue mass and are subjected to less signal averaging and cancellation effects. As a result, data acquisition with smaller electrodes allows for the accurate detection of very small amplitude signals while limiting the effects of far-field signals and background noise. This can be of particular advantage in the low-voltage zones and areas of heterogeneous scar distribution, where the increased mapping resolution offered by the multielectrode catheters allows identifying surviving myocardial bundles channels, otherwise considered dense scar by standard linear catheters (Fig. 6.15).^{9,28,31}

It is important to note that a minimal electrogram amplitude to identify an unexcitable scar has not yet been strictly defined. As different catheters with various electrode sizes and interelectrode spacings are becoming available, individualized validation is required, and catheter-specific thresholds are needed to improve scar characterization.

Vector of activation. The vector of propagation of the activation wavefront in relation to the two recording electrodes, and orientation of the recording electrode relative to the tissue, influences the degree of signal cancellation and therefore the resultant bipolar signal amplitude.²⁸

In multiple studies, significant differences in bipolar and unipolar low-voltage characterization of ventricular scar were frequently observed by varying the wavefront of ventricular activation. Activation within viable neighboring tissue can allow for greater variability in myocardial activation, resulting in wavefront fusion (additive to electrogram) and cancellation (subtractive from electrogram). Furthermore, local conduction delay or block and uncoupling between near- and far-field signals can potentially account for these observations. Mismatches between low bipolar voltage regions appear to occur most frequently in areas with predominantly mixed scar tissue (areas with electrogram amplitudes in the range of 0.5 to 1.5 mV) and in septal regions. Dense scar appears to be less sensitive to wavefront changes compared with mixed scars, likely due to lesser available mass of normal far-field myocardium to contribute to the electrogram signal within the field of view of the mapping catheter. Therefore voltage mapping during more than one activation sequence (e.g., during normal sinus rhythm [NSR] and ventricular pacing) can potentially increase the sensitivity to detect arrhythmogenic substrate.³²

Tissue contact. Voltage mapping relies heavily on consistent catheter contact. If catheter contact is suboptimal and falsely low voltage measurements are recorded, the voltage map will erroneously suggest a scar. The use of ICE and contact force sensors can help ensure adequate catheter contact.²⁸

Mapping density. Low mapping density is associated with the significant interpolation of data between sampled points. The use of multielectrode catheters enables rapid high-density voltage mapping through simultaneous multiple-point acquisition, which reduces interpolation of data between points and improves mapping accuracy.²⁸

eFig. 6.2 Endocardial Left Ventricular (LV) Electroanatomic Voltage Mapping. *Left*, Endocardial bipolar voltage map of the LV (left lateral view) showing low voltage areas (peak-to-peak bipolar amplitude less than 1.5 mV) in the basal lateral and apical walls. *Right*, Endocardial unipolar voltage map reveals more diffuse low voltage areas (unipolar amplitude of <8.3 mV) consistent with more extensive epicardial distribution of fibrosis. MA, Mitral annulus. Apex.

Fig. 6.15 Standard Electrode Versus Small Electrode for Delineation of Late Potentials in a Patient With Cardiomyopathy. Endocardial recordings from the inferolateral left ventricular free wall are shown from approximately the same location at almost the same time (two catheters in left ventricle). In (A) with a standard 3.5 mm distal tip, only far-field signals are recorded. In (B) with much smaller electrodes on a multipolar catheter, discrete high-frequency late potentials (red arrows) are observed (after end of QRS complex, red dotted line). Abl, Ablation; CS, coronary sinus.

Limitations of Electroanatomic Voltage Mapping

Electrogram amplitude is annotated to the electrogram peak. In regions of scar, far-field signals are frequently of larger amplitude than local electrograms. Therefore automated voltage annotation of the larger far-field electrograms can introduce errors in the voltage map, especially in scar regions (Fig. 6.16). Manual tagging of abnormal potentials or manual annotation of near-field electrogram voltage can help improve the map accuracy, but this can be challenging with high-density point acquisition.

Voltage mapping during NSR depends on the assumption that the arrhythmogenic substrate is limited to fixed myocardial scar and anatomical barriers. It is now well known that functional lines of block (present during tachycardia but not in NSR) play an important role in arrhythmogenesis, and these barriers cannot be detected by substrate mapping performed in NSR. Therefore conducting channels developing during arrhythmias and surrogates of channels and conduction barriers identified by substrate mapping in NSR may not correspond.³³

Even when conducting channels within the scar area can be identified by voltage mapping, their relationship to the arrhythmia circuit remains to be assessed by other mapping methods (e.g., entrainment mapping). Voltage mapping does not distinguish abnormal bystander

areas that are not involved in a tachycardia circuit from clinically relevant channels.³⁴

It is also important to recognize that the transmural distribution of the scar may not be reliably represented by voltage mapping from either the endocardial or epicardial surface. In particular, identifying septal or mid-myocardial substrates can be challenging.¹⁹

High-Resolution Electroanatomic Mapping

Current iterations of electroanatomic mapping systems allow the construction of high-resolution electroanatomic maps through catheters with multiple electrodes. These multielectrode mapping catheters facilitate the creation of high-density maps through simultaneous acquisition of points from multiple closely spaced electrodes. The rapid acquisition of a large quantity of data facilitates the generation of detailed, high-density, high-resolution activation and voltage maps. Further, the use of multielectrode mapping catheters helps expedite the process of data acquisition during electroanatomic mapping and decrease fluoroscopy and procedure times. Automated data acquisition and annotation can further facilitate the mapping process (with the previously noted caveats).^{10,20,29}

Several multielectrode catheters with varying configurations have been described. The EnSite NavX system can utilize any multielectrode catheter

Fig. 6.16 Epicardial Late Potential Obscured by Far-Field Signal in a Patient With Dilated Cardiomyopathy. The ablation catheter is on the epicardial surface after percutaneous pericardial access; a very large potential within the QRS complex (green arrow) will be taken by the mapping system to characterize the site as being “normal,” whereas distinct high-frequency late (red arrows) are evident well after the end of the QRS complex (dotted red line). Abl, Ablation; CS, Coronary sinus.

for data acquisition. The multipolar Lasso, PentaRay, and DecaNav catheters (Biosense Webster) are equipped with the electromagnetic sensor and can be used with the CARTO system, allowing for electroanatomical data acquisition. The circular Lasso catheter has 10 or 20 electrodes, each with a surface area of 1.0 mm², recording bipolar electrograms with an interelectrode spacing of 3 mm, and maximal diameter of 25 mm. The star-shaped multielectrode PentaRay is a 7 Fr steerable catheter (180 degrees of unidirectional flexion) with 20 electrodes distributed over five soft, radiating spines (1-mm electrodes separated by 4-4-4 or 2-6-2 mm edge-to-edge interelectrode spacing), thus allowing splaying of the catheter to cover a surface diameter of 3.5 cm (see Fig. 6.1; see Fig. 4.2). The spines have been given alphabetical nomenclature (A to E), and spines A and B are recognized by radiopaque markers. These multielectrode catheters have smaller electrodes (0.8 mm²) and closer interelectrode spacing (as compared with ablation catheters), which allow for recording bipolar signals from smaller tissue diameters that are less vulnerable to averaging and cancellation effects.^{20,31,35}

The Rhythmia system utilizes a mini-basket catheter (Orion), which has 64 very small electrodes (0.4 mm²) with interelectrode spacing of 2.5 mm (see Fig. 6.7). This catheter allows for the construction of ultra-high resolution activation and voltage maps.^{29,36}

Ripple Mapping

Ripple mapping is a novel visualization technique that displays time-voltage data as dynamic bars on the cardiac surface. Ripple mapping software requires incorporation of a 3-D electroanatomic mapping system (CARTO). Each electrogram component is visualized at its corresponding 3-D coordinate on the CARTO-generated chamber geometry as a dynamic surface bar that varies in height and color according to the electrogram voltage–time relationship that is time-gated to a selected fiduciary reference electrogram. Both positive and negative electrogram deflections are shown protruding outward from the surface. The height of each bar correlates with the voltage amplitude of the electrogram at that time point, without the need for annotation of local activation timing (Fig. 6.17).³⁷

When multiple points are collected over an area, adjacent bars move up and down (according to the local voltage) in a sequential fashion (in time relative to a chosen fiducial reference electrogram). As a result, a “ripple” effect is seen as the movement traverses from one bar to the next, creating a “ripple map.” Propagation of activation is visualized by the direction of the “ripple” on the map (Fig. 6.18). Ripple activation maps can be superimposed on a conventional bipolar voltage map, thereby displaying the surface geometry with both voltage and activation simultaneously.³⁸

Ripple mapping is designed to overcome some of the limitations of existing electroanatomic activation and voltage mapping. Electroanatomic mapping requires the accurate annotation of local activation time of electrograms within the window of interest. In the region of scar, annotation as a single activation time often is suboptimal, due to the presence of fractionated or multiple late potentials. Incorrect annotation of only a small number of electrograms can invalidate the entire activation map. Furthermore, the assignment of a single time value to an individual local potential within a multicomponent electrogram without indication of signal quality often ignores the information contained within complex fractionated electrograms that can be valuable for the identification of the arrhythmogenic substrate and ablation targets. Voltage mapping can also be challenging in the region of scar. Voltage annotation to the electrogram peak can erroneously incorporate far-field electrograms, which are frequently larger than the local signal. In addition, interpolation of data within unmapped regions can lead to the display of false information.

In contrast, ripple mapping preserves all components of the electrogram. Instead of assigning each point as a single time value to create a color-coded map, ripple mapping preserves and represents all the components of the electrogram (voltage, waveform, and timing) at its corresponding 3-D coordinate as a bar that rises perpendicular to the surface of the cardiac chamber that varies in height according to the underlying voltage amplitude, without the need for manual or automatic annotations of local activation timing or setting a window of interest (see Fig. 6.17). As a result, a sequence of small potential changes in a fractionated electrogram can be temporally linked to its adjacent neighbors, and delayed low-amplitude local activation within scar is seen distinct from an initial far-field electrogram occurring in tandem with activation in the surrounding healthy myocardium. Also, the system does not interpolate within unmapped regions; thus interpolation errors are avoided as only “real” data is displayed on the ripple map.^{38,39}

Although data are limited, several small studies demonstrated the potential value ripple mapping in determining activation patterns in both simple and complex cardiac rhythms.^{39,40}

Anatomical Mapping

All the recorded catheter locations are aggregated and used to create a shell (anatomical map) of the cardiac chamber. Modern electroanatomic

Fig. 6.17 Ripple Bar Height Versus Electrogram Voltage. The top panels (A to F) show increasing ripple bar height in correlation to the increasing magnitude of the corresponding electrogram voltage in the annotation window (*lower window*). Panel A shows the time-cursor (*white bar*) at an isoelectric point of the chosen electrogram (*lower panel*) with no visible corresponding ripple bar (*upper panel*). As the time-cursor moves along the electrogram, the bar always moves outward from the cardiac shell irrespective of whether it is a negative or positive bipolar electrogram polarity. Panel C represents deflection of the electrogram below the isoelectric line corresponding to a negative bipolar value (-0.86 mV); however, the bar is clearly protruding outward from the shell. The color can be correlated to the reference color bar seen to the left of the panel with low voltage represented by red and high voltage represented by purple. (From Jamil-Copley S, Linton N, Koa-Wing M, et al. Application of ripple mapping with an electroanatomic mapping system for diagnosis of atrial tachycardias. *J Cardiovasc Electrophysiol*. 2013;24:1361–1369.)

mapping systems incorporate utilities enabling computer-automated multipoint model creation while the mapping catheter is maneuvered around the anatomical structure (CARTO-3 Fast Anatomic Map Module and EnSite NavX Velocity One-Model Module). A virtual anatomical intracardiac geometry is obtained by moving the catheter in all directions throughout the cardiac chamber of interest, keeping contact with the endocardial wall to outline the structures. Points at the outermost boundaries are used to depict the outer geometry (shell), while points inbound to the outer shell are automatically removed. Acquired *activation* or *voltage* mapping points internal or external to the outer shell are included only if they fall within a *threshold* distance (defined by the user) from the outer surface. A purely anatomical map and catheter navigation capabilities are particularly suitable for ablation of arrhythmias with well-known substrates that can be treated by an anatomically based ablation approach, such as AFL and linear LA ablation for AF.

Electroanatomic maps represent the same anatomical map with an overlay of color-coded electrical data. Acquired *activation* or *voltage* mapping points internal or external to the outer shell are included only if they fall within a *threshold* distance (defined by the user) from the outer surface.

Acquired *activation* or *voltage* mapping points internal or external to the outer shell are included only if they fall within a *threshold* distance (defined by the user) from the outer surface. A purely anatomic map and catheter navigation capabilities are particularly suitable for ablation of arrhythmias with well-known substrates that can be treated by an anatomically based ablation approach, such as AFL and linear LA ablation for AF.

It is important to move the mapping catheter carefully and minimize inconsistency in the contact force on the catheter tip to avoid excessive

anatomical distortion and expansion of the virtual image. Such anatomical distortion can misrepresent the local fiducial sites, which should be taken into consideration when mapping and ablation are guided by fast anatomical maps.^{4,41}

Characteristic anatomical landmarks and sites of interest in the cardiac chamber are acquired and tagged. Valvular annuli, thoracic veins, and other structures can be marked and *carved* out of the electroanatomic map. If a CT reconstruction of the mapped cardiac chamber is available, the image can be visualized on a split screen and used to guide finer anatomical definition with the ablation catheter. On completion, maps can be edited to eliminate “false space” (i.e., geometry with sparse acquired points) and erroneous structure definition. Additional tagging of sites of interest and ablation points can be done during the procedure. Point-to-point activation mapping is carried out to create static isochronal, voltage, and activation maps (see Fig. 6.5).

Respiratory compensation is collected just before mapping to filter low-frequency cardiac shift associated with the breathing cycle. The CARTO-3 system enables automatic respiratory-gating for data acquisition through thoracic impedance measurement. With other systems, volume sampling with catheter movement during the exhalation phase can help reduce respiratory artifacts.

With the NavX system, a scaling algorithm (field scaling) can be applied to the completed detailed geometry to compensate for variations in impedance between the heart chambers and venous structures (which can otherwise result in a distortion of the *x-y-z* coordinates when a “roving” catheter is maneuvered among the regions of differing impedance). Field scaling is based on the measured interelectrode spacing for all locations within the geometry. Adjustments to the local strength of the navigation fields are made so that the computed catheter electrode

LEFT ATRIAL FOCAL TACHYCARDIA

Fig. 6.18 Ripple Map of Focal Atrial Tachycardia. Panels A to I demonstrate the centrifugal ripple bar propagation during a focal atrial tachycardia originating from the anterior wall of the left atrium. The map was created using CARTO and 1433 points collected in the left atrium. (From Jamil-Copley S, Linton N, Koa-Wing M, et al. Application of ripple mapping with an electroanatomic mapping system for diagnosis of atrial tachycardias. *J Cardiovasc Electrophysiol.* 2013;24:1361–1369.)

positions match the known interelectrode spacing of the catheters used to create the geometry.

The CARTO and Rhythmia systems require the use of proprietary catheters with a location sensor to collect mapping data and depict cardiac geometry. In contrast, NavX-guided procedures can be performed using any EP catheter.

Limitations of Anatomical Mapping

Significant anatomical distortions in complex structures can occur with low-density mapping, whereby individual interpolation schemes in the region of curvature do not depict the accurate geometry, especially at areas of exvaginations (e.g., the PVs, atrial appendages). This can be mitigated by (1) the acquisition of a larger number of points (increased density) to reduce the extent of interpolation; (2) the acquisition of a set of points at the critical junctions between the different anatomical structures; and (3) creating geometric shells of these structures in separate maps and then combining them into the main chamber.

In addition, a change in rhythm during the mapping procedure can alter cardiac geometry to the extent that anatomical points acquired during one rhythm cannot be relied on after a change in rhythm (Fig. 6.19). This is relevant during the mapping of PVCs (especially PVCs originating from the RV and those with short coupling intervals), because electrical and spatial information acquired during the arrhythmia can potentially be spatially separated from the same locations when they

are assigned during normal rhythm (e.g., at the time of RF delivery after tachycardia termination). Therefore, after termination of the arrhythmia, revisiting the site of early activation tagged during PVCs or tachycardia may not be feasible and can potentially be misleading as a target for ablation. This can be mitigated by annotating the site of interest after tachycardia termination before moving the mapping catheter from its original location.⁴²

Furthermore, electroanatomic mapping systems do not provide real-time correlation of catheter position and heart border motion. Therefore localizing the catheter tip against the virtual anatomical shell does not establish catheter tip-tissue contact, and other methods to confirm adequate electrode-tissue contact should be utilized (e.g., pacing and recording data at the catheter tip, intermittent fluoroscopic imaging, ICE, and force contact sensors). In fact, geometric reconstructions of the cardiac chamber during the same procedure can vary depending on the method used. For example, the 3-D ICE-derived LA geometric reconstruction was found to be smaller than reconstructions derived from electroanatomic mapping and merged CT images. During procedures lasting several hours, chamber sizes may change based on the accrual of 1 or more liters of saline infused.^{4,43}

Clinical Implications

Contemporary electroanatomic mapping systems provide the ability to visualize and navigate a complete set of intracardiac catheters in any

Fig. 6.19 Alteration of Cardiac Geometry by a Change in Cardiac Rhythm. CARTO electroanatomic activation map (color-coded) of the focus of the premature ventricular complexes (PVCs) in the right ventricular outflow tract (anterior view). The acquisition reference is set to the peak of the R wave in the surface ECG lead II. *Upper panel*, Electrical information (local activation time) is acquired by the CARTO system during activation mapping during the PVC. Spatial location of that point is acquired simultaneously (as indicated by the catheter location visualized on cardiac geometry, *red dot*). *Lower panel*, When the spatial location is acquired by the CARTO system during sinus rhythm (*blue dot*), the location of the ablation catheter is assigned to a spatially removed location of the virtual chamber model of the right ventricular outflow tract (RVOT; distance between the two points is 9 mm). Although the tip of the ablation catheter is maintained at the same anatomical location, the spatial information annotated on the virtual chamber model of the RVOT during sinus rhythm is removed and then tagged during the PVC. Therefore when the target of ablation is identified during PVCs, revisiting that target during sinus rhythm may not be accurate unless the acquired electroanatomical location during the PVC is also annotated (before moving the catheter from the identified ablation target) during sinus rhythm.

origin and macroreentrant tachycardia, precisely describing macroreentrant circuits and the sequence of activation during the tachycardia, understanding the reentrant circuit in relation to native barriers and surgical scars, identifying all slow-conducting pathways, rapidly visualizing the activation wavefront (propagation maps), and identifying appropriate sites for entrainment and pace mapping.

In addition, these systems provide a highly accurate geometric rendering of the cardiac chamber, with a straightforward geometric display having the capability to determine the 3-D location and orientation of the ablation catheter accurately. The position of the mapping electrode at any instant is readily apparent. The catheter can anatomically and accurately revisit a critically important recording site (e.g., sites with double potentials or those with good pace maps) identified previously during the study, even if the tachycardia is no longer present or inducible and map-guided catheter navigation is no longer possible. This accurate repositioning provides significant advantages over conventional techniques and is of great value in ablation procedures.

Sites of ablation energy application can be tagged, thus facilitating the creation of lines of block with considerable accuracy by serial RF lesion placement and allowing verification of the continuity of the ablation line and anatomical visualization of the remaining gaps, where additional RF applications can be delivered. This is of particular value after incomplete ablations caused by catheter dislocation, especially if these ablations had caused interruption of the target tachycardia. Additional RF applications can be delivered closely around an apparently successful ablation site to ensure elimination of the arrhythmogenic area. It also helps avoid repeated ablations at the same location.¹

Furthermore, fluoroscopy time and radiation exposure to the operator, the patient, and the laboratory staff can be substantially reduced (or even eliminated entirely) via electroanatomical catheter navigation, and the catheter can be accurately guided to positions removed from fluoroscopic markers.

Choice of Electroanatomic Mapping System

The choice of a specific mapping system for a particular interventional procedure is shaped by the importance of a specific characteristic in the mapping process, as well as the skill and experience of the operator. Advanced mapping systems have a limited role in the ablation of typical AFL, AVNRT, or bypass tracts (BTs), given the high success rate of the

cardiac chamber for diagnostic and therapeutic applications. Electroanatomic mapping systems integrate 3-D catheter localization with sophisticated complex arrhythmia maps and help associate relevant EP information with the appropriate spatial location in the heart and the ability to study activation patterns with high spatial resolution during tachycardia in relation to normal anatomical structures and areas of scar. This significantly facilitates defining the mechanisms underlying the arrhythmia, making a rapid first-pass distinction between a focal

conventional approach. However, for more complex arrhythmias, such as AT, AF, and VT, advanced mapping modalities offer a clear advantage. In addition, electroanatomic mapping systems can potentially shorten procedural time, reduce radiation exposure, and enhance the success rate for the ablation of wide spectrum of arrhythmias.

All three systems perform well for mapping of sustained arrhythmias and for substrate-based ablation procedures. On the other hand, mapping nonsustained arrhythmias, PACs, or PVCs can be tedious with each of these three mapping systems because of the need for sequential data acquisition. However, differences in methods of map acquisition between systems may affect procedure length and radiation use. The use of multielectrode mapping catheters (e.g., PentaRay or Orion) can expedite the mapping process.⁴⁴

Nonetheless, it is important for the electrophysiologist to be cognizant of the distinct advantages and shortcomings of each system.

CARTO

Although all three electroanatomic mapping systems demonstrate a high level of intrinsic accuracy, the magnetic field localization technology of CARTO appears to have superior accuracy at point localization performance and fewer problems with interstructure delineation as compared with impedance-based systems. Another advantage of using magnetic fields for catheter localization is that the fields remain stable over time and are unaffected by biological material; hence the localization accuracy of CARTO is less subject to inhomogeneous tissue characteristics. Electrical field distortions seen with EnSite NavX do not occur with CARTO.^{44,45}

A limitation of the CARTO system is the requirement of a special Biosense Webster catheter with a location sensor embedded proximal to its tip. No other catheter types may be used for electroanatomical data acquisition. Furthermore, the magnetic signal necessary for the CARTO system can potentially create interference with other EP laboratory recording systems. Defibrillators and pacemakers are safe with the system, but the magnetic field can prevent device communication with its programmer, and the magnetic field may need to be disabled temporarily to allow device programming. Percutaneous LV assist devices can cause interference and distortion on the mapping system. Magnetic fields used with the Stereotaxis remote magnetic navigation system are not problematic for the CARTO system.

Although CARTO-3 allows current-based visualization of EP catheters without magnetic sensors, the visualization of catheters is confined into a 3-D virtual area (matrix) that can be built only by using a magnetic sensor-equipped manufacturer-specific catheter. Furthermore, the system still cannot process electrical or location data from the nonproprietary catheters (i.e., catheters without magnetic sensors) to build the virtual geometry or for mapping purposes.²

Importantly, the coordinates of the magnetic field of CARTO are linked to the table and not the patient's body. Therefore significant movement of the patient can cause uncorrectable shifts requiring remapping.

EnSite NavX

One of the principal advantages of this system is its open platform. EnSite NavX enables the display in real time up to 128 electrodes simultaneously on multiple EP catheters with almost every commercially available catheter, including pacemaker leads. This system works with most manufacturers' ablation catheters, RF generators, and cryogenerators. The EnSite System can also be integrated with the Sensei robotic catheter system (Hansen Medical, Mountain View, CA, United States), allowing completely remote catheter navigation.

Also, unlike with the CARTO and Rhythmia, anatomic and electrical data (voltage or activation) can be acquired simultaneously by the EnSite

NavX system from multiple poles on all catheters utilized during the study (and not just catheters with magnetic sensors). Data acquisition can be augmented by the addition of a multielectrode array (MEA) for noncontact mapping.

A unique advantage of the EnSite system is that it can locate the position of the catheters from the puncture site to the final destination in the heart. Therefore all catheters can be navigated to the heart under guidance of the EnSite NavX system, and the use of fluoroscopy can be minimized for preliminary catheter positioning. This contrasts with CARTO-3 that enables visualization of EP catheters without magnetic sensors only when positioned within the 3-D matrix built only by using a magnetic sensor-equipped catheter.

Furthermore, NavX technology is partially insensitive to potential patient movements, as the coordinate system (patches) are linked to the patient, and therefore they move simultaneously with the patient, preventing map shifts.²

On the other hand, the impedance-based localization system used by EnSite is subject to changes in tissue properties. Changes in the respiration pattern and volume shifts during the course of the procedure (e.g., secondary to saline infusion when using an irrigated ablation) can cause impedance changes inside the body and potentially impact the localization accuracy of the EnSite system.^{44,45} The newer version of EnSite (EnSite Precision) now uniquely combines impedance and magnetics, which can enhance navigation and model creation.

Rhythmia

The main advantage of Rhythmia is the ability to create ultra-high-resolution activation and voltage maps using rapid and accurate automated data acquisition and annotation. The very small size of the electrodes on the Orion catheter minimizes far-field signals and background noise and allows accurate detection of very small amplitude signals. Also, this system offers the ability to change the mapping window in retrospect (see Fig. 6.10).

Similar to the EnSite system, Rhythmia can acquire electroanatomical data from magnetically enabled catheters (Orion and ablation catheters) as well as catheter without magnetic sensors. Data acquisition from catheters without magnetic sensors can be acquired only after construction of the electromagnetic field using magnetically enabled catheters. Notably, Rhythmia does not allow for integration with CT or MRI.^{6,36}

This mapping technology is preferentially designed for complex cardiac arrhythmias like AF, macroreentrant atrial tachycardia (MRAT), and scar-related VT, especially for substrate analysis (voltage maps), and analysis of conduction pattern (activation maps), but also for maps promoting effective catheter ablation (e.g., mapping gap in ablation lines). However, further studies are required to explore the potential clinical benefits gained from such ultra-high-density mapping.¹²

ENSITE NONCONTACT MAPPING SYSTEM

Fundamental Concepts

The noncontact mapping system (EnSite Array, St. Jude Medical) consists of a catheter-mounted MEA, which serves as the probe, a custom-designed amplifier system, a computer workstation used to display 3-D maps of cardiac electrical activity, and a conventional ablation catheter.⁴⁶

The MEA catheter consists of a 7.5-mL ellipsoid balloon mounted on a 9 Fr catheter around which is woven a braid of 64 insulated 0.003-mm-diameter wires (eFig. 6.3). Each wire has a 0.025-mm break in insulation that serves as a noncontact unipolar electrode. The system acquires more than 3000 noncontact unipolar electrograms from all points in the chamber simultaneously. The unipolar signals are recorded using a ring electrode located on the shaft of the array catheter as a

eFig. 6.3 Multielectrode Array for Noncontact Endocardial Mapping.

reference. The raw far-field EP data acquired by the array catheter are fed into a multichannel recorder and amplifier system that also has 16 channels for conventional contact catheters, 12 channels for the surface ECG, and pressure channels. Using data from the 64-electrode array catheter suspended in the heart chamber, the computer uses sophisticated algorithms to compute an inverse solution to determine the activation sequence on the endocardial surface.^{46,47}

The EnSite 3000 mapping system is based on the premise that endocardial activation creates a chamber voltage field that obeys the Laplace equation. Therefore when one 3-D surface of known geometry is placed within another of known geometry, if the electrical potential on one surface is known, then the potential on the other can be calculated. Because the geometry of the balloon catheter is known, and the geometry of the cardiac chamber can be reconstructed during the procedure (see later), endocardial surface potential can then be determined once the potentials over the balloon catheter are recorded. Using this concept, the raw far-field EP data acquired by the array catheter, which are generally lower in amplitude and frequency than the source potential of the endocardium itself and therefore have limited usefulness, are mathematically enhanced and resolved. The inverse solution to Laplace equation using the boundary element method predicts how a remotely detected signal by the MEA would have appeared at its source, the endocardial surface, so that electrograms are reconstructed at endocardial sites in the absence of physical electrode contact at those locations (“virtual electrograms”). Once the potential field has been established, more than 3000 activation points can be displayed as computed electrograms or as isopotential maps. The activation time at each endocardial site is determined by taking the time instant with maximum negative time derivative ($-dV/dt$) on the electrogram.⁴⁸

The system can locate any conventional mapping-ablation catheter in space with respect to the array catheter (and thus with respect to the cardiac chamber being mapped). A low-current (5.68 kHz) locator signal is passed between the contact catheter electrode being located and reference electrodes on the noncontact MEA. This creates a potential gradient across the array electrodes, which is then used to position the source. This locator system is also used to construct the 3-D computer model of the endocardium (virtual endocardium) that is required for the reconstruction of endocardial electrograms and isopotential maps. This model is acquired by moving a conventional contact catheter around the endocardial surface of the cardiac chamber; the system collects the location information, thus building up a series of coordinates for the endocardium and generating a patient-specific, anatomically contoured model of its geometry. During geometry creation, only the most distant points visited by the roving catheter are recorded to ignore those detected when the catheter is not in contact with the endocardial wall.

Using mathematical techniques to process potentials recorded from the array, the system can reconstruct more than 3000 unipolar electrograms simultaneously and superimpose them onto the virtual endocardium, thus producing isopotential maps with a color range representing voltage amplitudes. In addition, the locator signal can be used to display and track the position of any catheter on the endocardial model (virtual endocardium) and allows the marking of anatomical locations identified using fluoroscopy and electrographic characteristics. During catheter ablation procedures, the locator system is used in real time to navigate the ablation catheter to sites of interest identified from the isopotential color maps, catalog the position of RF energy applications on the virtual endocardium, and facilitate revisitation of sites of interest by the ablation catheter.

In addition, the EnSite software provides the capability of point-to-point contact mapping, to allow the creation of activation and voltage maps by acquiring serial contact electrograms and displaying them on

the virtual endocardium (see later). This is useful for adding detail, familiarity, and validation of the information obtained by the noncontact method.

Technology Application

The EnSite 3000 system requires placing a 9 Fr MEA and a mapping-ablation catheter. To create a map, the balloon catheter is advanced over a 0.035-inch guidewire under fluoroscopic guidance into the cardiac chamber of interest. For RA arrhythmias, the guidewire is advanced into the SVC, and the balloon is deployed in the upper third of the RA for tachycardia originating in the SVC, in the middle third for ectopic AT, and in the lower third for typical AFL. For LA arrhythmias, the guidewire is advanced into the left superior PV, and the balloon is deployed in the middle of the LA. For RV arrhythmias, the guidewire is advanced into the pulmonary artery, and the balloon is deployed close to the right ventricular outflow tract (RVOT) or in the middle of the RV. The balloon can be filled with contrast dye, thus permitting it to be visualized fluoroscopically (see Chapter 23, eFig. 23.9). Except in the RVOT, the balloon is positioned in the center of the cardiac chamber of interest and does not come in contact with the walls of the chamber being mapped. In addition, the position of the array in the chamber must be secured to avoid significant movement that would invalidate the electrical and anatomical information. The array must be positioned as closely as possible (and in direct line of sight through the blood pool) to the endocardial surface being mapped, because the accuracy of the map is sensitive to the distance between the center of the balloon and the endocardium being mapped.⁴⁶

During the use of this mapping modality, systemic anticoagulation is critical to avoid thromboembolic complications. Intravenous (IV) heparin is usually given to maintain the activated clotting time longer than 250 seconds for right-sided and longer than 300 seconds for left-sided mapping.

A conventional (roving) deflectable mapping catheter is also positioned in the chamber being mapped and used to collect geometry information. The mapping catheter is initially moved to known anatomical locations, which are tagged. A detailed geometry of the chamber is then reconstructed by moving the mapping catheter and tracing the contour of the endocardium (using the locator technology). To create detailed geometry, attempts must be made to make contact with as much endocardium as possible. This requires maneuvering on all sides of the array, which can be challenging and can require decreasing the profile of the balloon by withdrawing a few milliliters of fluid. This results in the rapid formation of a relatively accurate 3-D geometric model of the cardiac chamber. The creation of chamber geometry can be performed during sinus rhythm or tachycardia.

Once the chamber geometry has been delineated, tachycardia is induced and mapping is started. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. Following this, the segment must be analyzed by the operator to find the early activation during the tachycardia (Fig. 6.20).⁴⁶

The noncontact mapping system is capable of simultaneously reconstructing more than 3360 unipolar electrograms and superimposing them onto the virtual endocardium. From these electrograms, isopotential or isochronal maps can be reconstructed (see Fig. 6.20). In isopotential mapping, unlike isochronal mapping, activation is assumed to occur when the electrogram voltage reaches a predefined magnitude. Because of the high density of data, color-coded isopotential maps are used to depict graphically regions that are depolarized, and wavefront propagation is displayed as a user-controlled 3-D “movie” (Fig. 6.21). The color range represents the voltage or timing of onset of the electrogram. The highest chamber voltage is at the site of origin of the

Fig. 6.20 Noncontact Mapping of Idiopathic Right Ventricular Outflow Tract (RVOT) Tachycardia. (A) Right anterior oblique and right lateral views of color-coded isopotential map of RVOT activation during a single premature ventricular complex (PVC). (B) Surface electrocardiographic (white) and intracardiac contact (blue) and virtual noncontact (yellow, V_1 - V_1 through V_1 - V_4) electrograms are shown during the PVC. Inset, Virtual electrograms at the site of earliest activation (note the QS pattern).

electrical impulse. Although the electrode closest to the origin of the impulse is influenced the most, all the electrodes on the array catheter are influenced, with the degree of influence diminishing with the distance between the electrode and each endocardial point.⁴⁶

In addition, the system can simultaneously display as many as 32 electrograms as waveforms (see Fig. 6.20). Unipolar or bipolar electrograms (virtual electrograms) can be selected at any given interval of the tachycardia cycle by using the cursor from any part of the created geometry and displayed as waveforms as if from point, array, or plaque electrodes. The reconstructed electrograms are subject to the same electrical principles as contact catheter electrograms because they contain far-field electrical information from the surrounding endocardium, as well as the underlying myocardium signal vector, and distance from the array may affect the contribution to the electrogram. These selected unipolar waveforms are used to augment information obtained from the 3-D map by demonstrating the slope of depolarization, the presence of double potentials or fractionation, and differentiation of far-field signals from more relevant endocardial activation.

In the unipolar electrogram, signals associated with high conduction velocity (e.g., the His-Purkinje system) possess a greater slope ($-dV/dt$), and thus are characterized by high-frequency spectral components

(more than 32 Hz). Electrograms recorded in normally conducting atrial or ventricular myocardium possess spectral components in the midrange from 4 to 16 Hz, whereas electrograms in regions of slow conduction are composed of lower frequency spectral components from 1 to 4 Hz. Thus the high-pass filter must be adjusted between 1 and 32 Hz, helping modulate the extent to which low-frequency signals are visible on the 3-D display. The identification of true local activation and its differentiation from the far-field signals are essential to the successful utilization of noncontact mapping. The true local activation always shows advancement of isopotential lines, but far-field signals would show retraction of isopotential lines on the 3-D display when electrograms are traced in their entirety.

When analyzing noncontact activation map data to locate the site of origin of a focal arrhythmia, two distinct sites can be marked at the onset of electrical activity: earliest activation and breakout sites. The earliest activation site is defined as the site with the earliest unipolar deflection from baseline during tachycardia, forming a single spot on the isopotential map, as well as characterized by a QS pattern of non-contact unipolar electrogram. The breakout site is marked as the site

Fig. 6.21 Noncontact Isopotential Maps of Typical Atrial Flutter. Right atrial shell is displayed in right anterior oblique (RAO, left panels) and left anterior oblique projections (LAO, right panels). Wavefront activation sequence is tracked on the isopotential map throughout the tachycardia cycle (burning red star surrounded by white and red circles) propagating in a counterclockwise pattern (from A to D) around the tricuspid annulus (TA).

along the depolarization pathway identified by the color-coded activation map where rapid centrifugal electrical propagation originated from and local unipolar electrograms exhibited the maximum $-dV/dt$. For the identification of earliest activation and breakout sites, a broad color band setting is used with color high (defined as unipolar electrogram baseline) at -0.1 mV and color low at -2 mV. The virtual unipolar high-pass filter is set to 4 Hz. While earliest activation and breakout sites (that may be separated by ≥ 1 cm) appear to be associated with similar pace map scores and endocardial bipolar activation prematurity in relation to the onset of the tachycardia complex, one study found that the earliest activation site was a more sensitive marker for the true site of origin of the VT/PVC, as evident by the greater likelihood of achieving acute ablative success.⁴⁹

Substrate mapping based on scar or diseased tissue has been introduced to the noncontact mapping technology. High-density voltage mapping of the atrial substrate is performed using the peak negative voltage of the reconstructed unipolar electrograms. Areas with slow conduction are identified along the reentrant circuit of the atypical AFL. An atrial substrate characterized by an abnormally low peak negative voltage can potentially predict areas with slow conduction during macroreentrant tachycardias, which would provide a substrate for reentry.

Clinical Implications

The MEA has been successfully deployed in all four cardiac chambers by using a transvenous, transeptal, or retrograde transaortic approach to map atrial and ventricular tachyarrhythmias.⁴⁸

The biggest advantage of noncontact endocardial mapping is its ability to recreate the endocardial activation sequence from simultaneously acquired multiple data points over a few (theoretically one) tachycardia beats, without requiring sequential point-to-point acquisitions, thus obviating the need for prolonged tachycardia episodes that the patient might tolerate poorly. This technique can be used to map non-sustained arrhythmias; PACs; PVCs; rhythms that are not hemodynamically stable, such as very rapid VT (see Fig. 6.20); and possibly irregular rhythms such as AF or polymorphic VT. The system generates isopotential maps of the endocardial surface at successive cross sections of time, and when these are animated, the spread of the depolarization wave can be visualized. These maps are particularly useful for identifying rapid breakthrough points and slowly conducting macroreentrant pathways, such as the critical slow pathways in ischemic VT or reentrant AT in patients with surgically corrected congenital heart disease. In macroreentrant tachycardias such as typical AFL or VT, the reentry circuit can be fully identifiable, along with other aspects, such as the slowing, narrowing, and splitting of activation wavefronts in the isthmus (see Chapter 12, eFig. 12.5; Fig. 6.21). The system can also map multiple cardiac cycles in real time, a method that discloses changes in the activation sequence from one beat to the next. Because mapping data are acquired without direct contact of conventional electrode catheters with the endocardium, the use of noncontact mapping can help avoid the mechanical induction of ectopic activity that is frequently seen during conventional mapping. An additional advantage of this system is that any catheter from any manufacturer can be used in conjunction with this mapping platform. Other useful features include radiation-free catheter navigation, revisitation of points of interest, and cataloging ablation points on the 3-D model.⁴⁶

In complex substrate-related arrhythmias, the use of activation mapping alone may not be sufficient for rhythm analysis or identifying ablation targets. Substrate mapping based on scar or diseased tissue is of value in these cases. Although substrate mapping used to be relatively limited with the noncontact mapping technology (very low amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and endocardial surface exceeds 40 mm),

dynamic substrate mapping allows the creation of voltage maps from a single cardiac cycle (in contrast to the contact mapping system, in which the mapping catheter is moved point to point over the endocardial surface). Dynamic substrate mapping also provides the capability of identifying low-voltage areas, as well as fixed and functional block, on the virtual endocardium through noncontact methods, provided that points more than 40 mm from the electrode array are excluded from analysis. Combining substrate mapping with the ability of the noncontact system to assess activation over a broad area from a single beat may facilitate the ablation of hemodynamically unstable or nonsustained macroreentrant tachycardias.

Limitations

The overall accuracy of the reconstructed electrograms decreases with the distance of the area mapped from the array catheter, thus creating problems in mapping large cardiac chambers. Virtual electrogram quality deteriorates at a distance exceeding 4 cm from the array catheter and at polar regions. Therefore the array must be positioned as closely as possible to the endocardial area of interest, and at times it can be necessary to reposition the array catheter to acquire adequate isopotential maps.

Only data segments up to a maximum of 10 seconds in length can be stored retroactively by the EnSite system once the record button has been pushed. Thus continuous recording and storage of all segments of an arrhythmia are not possible at the time of evaluation of the arrhythmia maps. Therefore some isolated PACs or PVCs that can be of interest during evaluation and mapping could be missed. In addition, the acquired geometry with the current version of software is somewhat distorted, requiring multiple set points to establish the origin and shape of complicated structures such as the LA appendage or PVs clearly. Otherwise these structures can be lost in the interpolation among several neighboring points. In addition, synchronized mapping of multiple chambers requires multiple systems. Importantly, maps are highly sensitive to the changes in filtering frequencies used in postprocessing analysis.⁴⁸

Because the geometry of the cardiac chamber is contoured at the beginning of the study during sinus rhythm, changes of the chamber size and contraction pattern during tachycardia or administration of medications (e.g., isoproterenol) can adversely affect the accuracy of the location of the endocardial electrograms. Moreover, because isopotential maps are predominantly used, ventricular repolarization must be distinguished from atrial depolarization and diastolic activity. Early diastole can be challenging to map during VT.

Sometimes it is difficult to manipulate the ablation catheter around the outside of the balloon, especially during mapping in the LA. Special attention and care also are necessary during the placement of the large balloon electrode in a relatively small cardiac chamber. Another disadvantage is that the balloon catheter cannot be moved after the completion of geometry creation because it will change the activation localization and result in distortion of isopotential maps.

Although the risk of complications is low, aggressive anticoagulation measures because of balloon deployment in the cardiac chamber expose patients to potential bleeding complications.

BASKET CATHETER MAPPING

Fundamental Concepts

The basket catheter mapping system consists of a basket catheter (Constellation, Boston Scientific, Natick, MA, United States), a conventional ablation catheter, the Astronomer (Boston Scientific), and a mapping system.

The basket catheter consists of an open-lumen catheter shaft with a collapsible, basket-shaped, distal end. Currently, baskets are composed

B

eFig. 6.4 Basket Catheter Mapping During Focal Atrial Tachycardia (AT). (A) Simultaneous recordings of the surface ECG leads I and aVF and 56 bipolar electrograms from the basket catheter in a patient with focal AT. The first beat is a sinus beat. The next three beats are tachycardia beats. His bundle (H) potential is recorded in electrode pairs F2/3 and F3/4. The earliest spot of activation during sinus rhythm (SR) and AT is shown (asterisks). Spline A was located in the anterolateral right atrium (RA), splines B and C in the lateral region, splines D and E in the posterior region, and splines G and H across the tricuspid valve. The activation times are marked with red bars. (B) *Upper panel*, Animated map of the SR beats. *Lower panel*, Animated map of the AT beats. Planar and three-dimensional options are shown. During SR, the impulse emerged in the high lateral area (spline B1-B2) and propagated rapidly down the lateral wall. The complete activation of the RA took 85 milliseconds. During focal AT, the earliest activity emerged in the midposterior wall (spline E4-E5). The activation sequence of the RA was entirely different from that of SR. The complete activation of the RA took 95 milliseconds. CL, Cycle length. (From Zrenner B, Ndrepepa G, Schneider M, et al. Computer-assisted animation of atrial tachyarrhythmias recorded with a 64-electrode basket catheter. *J Am Coll Cardiol*. 1999;34:2051.)

of 64 platinum-iridium ring electrodes mounted on eight equidistant, flexible, self-expanding nitinol splines (metallic arms; see Fig. 4.3). Each spline contains eight 1.5-mm electrodes equally spaced at 4 or 5 mm apart, depending on the size of the basket catheter used. Each spline is identified by a letter (from A to H) and each electrode by a number (distal 1 to proximal 8). The basket catheter is constructed of a superelastic material to allow passive deployment of the array catheter and optimize endocardial contact. The size of the basket catheter used depends on the dimensions of the chamber to be mapped, and it requires antecedent evaluation (usually by echocardiogram) to ensure proper size selection.

The mapping system consists of an acquisition module connected to a computer, which is capable of simultaneously processing bipolar electrograms from the basket catheter, 16 bipolar-unipolar electrogram signals, a 12-lead ECG, and a pressure signal. Color-coded activation maps are reconstructed online. The color-coded animation images simplify the analysis of multielectrode recordings and help establish the relation between activation patterns and anatomical structures (eFig. 6.4). The electrograms and activation maps are displayed on a computer monitor, and the acquired signals can be stored on optical disk for off-line analysis. Activation marks are generated automatically with a peak or slope (dV/dt) algorithm, and activation times are then edited manually as needed.

Technology Application

The size of the cardiac chamber of interest is initially evaluated, usually with echocardiography, to help select the appropriate size of the basket catheter. The collapsed basket catheter is advanced under fluoroscopic guidance through a long sheath into the chamber of interest; the sheath is then withdrawn to expose several electrodes at the tip of the catheter (such that the exposed portion is flexible rather than stiff) and the catheter is then advanced and allowed to expand. Electrical-anatomical relations are determined by fluoroscopically identifiable markers (spline A has one marker and spline B has two markers located near the shaft of the basket catheter) and by the electrical signals recorded from certain electrodes (e.g., ventricular, atrial, or HB electrograms), which can help identify the location of those particular splines (Fig. 6.22).

From the 64 electrodes, 64 unipolar signals and 32 to 56 bipolar signals can be recorded (by combining electrodes 1-2, 3-4, 5-6, 7-8, or

1-2, 2-3 until 7-8 electrodes on each spline). Color-coded activation maps can be reconstructed (see eFig. 6.4). The concepts of activation mapping discussed earlier are then used to determine the site of origin of the tachycardia.

The electrograms recorded from the basket catheter can be used to monitor changes in the activation sequence in real time and thereby indicate the effects of ablation as energy applications are made. The capacity of pacing from most basket electrodes allows the evaluation of activation patterns, pace mapping, and entrainment mapping.

Clinical Implications

The multielectrode endocardial mapping system allows simultaneous recording of electrical activation from multiple sites and fast reconstruction of endocardial activation maps. This can limit the time endured in tachycardia compared with single point-mapping techniques without the insertion of multiple electrodes. It also facilitates the endocardial mapping of hemodynamically unstable or nonsustained tachycardias. Importantly, the recording of only a single beat can be sufficient to enable analysis of the arrhythmogenic substrate.

Endocardial mapping with a multielectrode basket catheter has been shown to be feasible and safe for various arrhythmias, including AT, AFL, VT, and PV isolation (see eFig. 11.8). However, in view of more advanced mapping systems, and because of significant limitations of the current basket catheters, its use has been limited.

Limitations

Because of its poor spatial resolution, the basket catheter in its current iteration has demonstrated only limited clinical usefulness for guiding ablation of reentrant atrial or ventricular arrhythmias. The relatively large interelectrode spacing in available catheters prevents high-resolution reconstruction of the tachycardia and is generally not sufficient for a catheter-based ablation procedure, given the small size and precise localization associated with RF lesions. In addition, the quality of recordings is critically dependent on proper selection of the basket size. Resolution is limited to the proportion of electrodes in contact with the endocardium and by unequal deployment and spacing of the splines; in addition, electrodes are not evenly distributed on the splines (no electrodes on the proximal 30% of each spline). Unfortunately the electrode array does not expand to provide adequate contact with the

Fig. 6.22 Fluoroscopic Appearance of the Constellation Basket Catheter in the Superior Vena Cava. (A) Right anterior oblique view (RAO). (B) Left anterior oblique view (LAO). A decapolar catheter is positioned in the coronary sinus (CS). Dual chamber pacemaker leads are implanted in the right atrial appendage (RAA) and right ventricle. Note the radiopaque electrodes on the splines of the basket catheter. Spline B can be identified on fluoroscopy by the two markers located near the shaft of the basket catheter (arrows). An ablation catheter is positioned at the proximal aspect of spline A.

entire cardiac chamber; therefore good electrode contact at all sites on the endocardium is difficult to ensure because of irregularities in the cardiac chamber surface, so that areas crucial to arrhythmia circuit or focus may not be recorded. Moreover, regions such as the right and left atrial appendages and CTI are incompletely covered by the basket catheter. As a result, arrhythmia substrates involving these structures are not recorded by the basket catheter.

Voltage, duration, and late potential maps are not provided by this mapping approach. In addition, basket catheter mapping does not permit immediate correlation of activation times to precise anatomical sites, and a second mapping-ablation catheter is still required to be manipulated to the site identified for more precise mapping and localization of the target for ablation, as well as for RF energy delivery. Basket catheters also have limited torque capabilities and limited maneuverability, which hamper correct placement, and they can abrade the endocardium.

Carbonizations occasionally observed after ablation on the splines of the basket catheter can potentially cause embolism. Carbonization, which appears as dark material attached to the basket catheter electrodes or splines, are thought to be caused by the concentration of RF energy on the thin splines that results in very high local temperatures that induce the denaturation of proteins. Carbonization can be greatly diminished with the use of an irrigated tip catheter, as opposed to conventional ablation catheters; complete avoidance is difficult if the basket is deployed in the region of interest for ablation.

FOCAL IMPULSE AND ROTOR MAPPING

Focal impulse and rotor modulation (FIRM) mapping is a novel spatiotemporal mapping system (RhythmView, Abbott, Chicago, IL, United States) that uses a 64-electrode basket catheter (eight splines with eight electrodes per spline) for biatrial panoramic contact mapping of AF.

FIRM mapping has been used to identify patient-specific AF drivers—that is, regions in the atrium that may be responsible for maintaining AF, to design tailored ablation strategies. FIRM mapping records AF unipolar electrograms in a wide field-of-view across the majority of both atria and then employs physiologically directed computational methods to create activation trails, which can identify putative regions of recurrent organized rotational activity (rotors) and focal sources (focal drivers) within the atria, which appear to have a mechanistic role in sustaining human AF.^{50,51}

Wide-area contact mapping uses monophasic action potentials to separate potentially reproducible elements (principal components) of activation in AF from bystander disorganized activation in a clinically meaningful fashion. Basket catheter data are exported to RhythmView, which filters out QRS complexes and T waves and analyzes the unipolar atrial electrograms, taking into account rate-dependent refractoriness (“restitution”) and conduction slowing to determine physiologically plausible activation paths. The resulting computational phase maps depict putative propagation of electric activity during AF, displayed as a gray-scale animation. Rotors are defined as phase singularities with emanating spiral waves that disorganize in surrounding tissue. Repetitive focal drivers are defined as activation emanating centrifugally from a source region. Clinically rotors or focal drivers observed in FIRM maps are diagnosed as AF sources only if they lie in a spatially reproducible location (i.e., showing spatial stability) for minutes (i.e., showing temporal stability). This definition excludes transient or migratory activity that would be difficult to target for ablation.^{52,53}

Technology Application

Initially, atrial geometry is constructed using an electroanatomic mapping system (EnSite NavX or CARTO). Then the 64-pole basket catheter (Constellation, Boston Scientific; or FIRMap, Abbott, Chicago, IL, United

States) is advanced through a long sheath from the femoral vein sequentially into the RA and then (transseptally) into the LA. The size of the basket catheter is selected according to LA dimensions (as measured on preprocedural imaging or intraprocedural ICE). The basket catheter is manipulated to ensure good electrode contact and electrode locations are verified within the atrial geometry using fluoroscopy or electroanatomic mapping. Upsizing the basket catheter needs to be considered when optimal endocardial coverage (greater than 75% of either atrial surface) by basket catheter electrodes cannot be achieved. Downsizing the basket size should be considered when excessive basket distortion or insufficient basket expansion occurs. IV heparin is infused to achieve an activated clotting time of more than 350 seconds.⁵⁴

FIRM mapping is performed during spontaneous or induced AF. Unipolar and bipolar atrial electrograms from the basket catheter are filtered at 0.05 to 500 Hz and recorded at 1-kHz sampling frequency. Unipolar electrograms are recorded during AF for 1 minute and exported to a dedicated proprietary mapping system (RhythmView). Multiple 1-minute recordings are typically analyzed over a period of 5 to 10 minutes. Using phase-based algorithms, RhythmView software provides 2-D maps of AF propagation (isopotential movies and isochronal activation maps) projected onto grids. AF (FIRM) maps are analyzed intra-procedurally to guide ablation.

Electrical rotors are defined as phase-mapped rotation around a center of rotation, while focal impulses showed centrifugal activation from a source, both with precession (“wobble”) and complex surrounding breakdown that obscure fibrillatory sources on simple activation maps (Fig. 6.23). Rotors and focal impulses are considered AF sources only if they lay in reproducible regions, with precession, on repeated analysis for thousands of cycles.^{50,54,55}

Based on basket grid coordinates, referenced to electrode positions on electroanatomic shells, the ablation catheter is manipulated within the area indicated by the FIRM map as the center of rotation (for rotors) or focal impulse origins that are targeted by RF application. Following ablation, remapping is performed to confirm rotor elimination.⁵⁰

Clinical Implications

Initial studies using FIRM showed that rotors and focal sources are present in the vast majority of patients with AF.⁵¹ Ablation of AF drivers as guided by FIRM, in the form of small number of stable rotors or focal sources distributed in both atria and frequently located outside the PV ostia, resulted in high rates of acute termination and long-term freedom from recurrent AF. However, subsequent studies failed to replicate the findings of initial reports with some reporting a low acute procedural success in nonparoxysmal AF population after targeting the FIRM-identified rotors and very high long-term arrhythmia recurrence as compared with conventional approaches to AF ablation. Other reports with more extensive experience are more encouraging. Therefore the strategy of rotor ablation as guided by FIRM remains controversial, given the lack of randomized data supporting its efficacy and safety.⁵⁴

Limitations

FIRM mapping has several limitations. The basket catheter may provide inadequate coverage of both atria, although catheters chosen for LA mapping generally work well in the RA. Rotors arising in appendages and PVs could appear as foci at breakout sites. Interpretation of maps for targeting sources can be challenging, and there are as yet no standards for geographic extent of ablation or endpoints (i.e., complete elimination of electrograms vs. amplitude reduction).

Furthermore, studies showed that FIRM-identified rotor sites did not differ quantitatively or mathematically from other atrial sites, and did not appear to exhibit distinctive EP characteristics that would allow for prediction of ablation success.⁵²

Successful repeat catheter ablation of recurrent longstanding persistent atrial fibrillation with rotor elimination as the procedural endpoint: a case series. *J Cardiovasc Electrophysiol.* 2016;27:274–280.)

STEREOTAXIS MAGNETIC NAVIGATION SYSTEM

Fundamental Concepts

Catheter navigation by magnetic force was initially introduced in the early 1990s for diagnostic studies in neonates. However, the development of conventional steerable electrodes with integrated pull wires to deflect the catheter tip facilitated the current technique for catheter ablation. This conventional technique is limited by the fixed maximal catheter deflection and relies mostly on the skill of the operator to ensure stable catheter positioning. A novel magnetic navigation system (MNS; 0.15 T, Telstar, Stereotaxis, St. Louis, MO, United States) was introduced to clinical practice. It was proven to be a safe and feasible tool for catheter ablation, although it did not allow remote catheter ablation. The second-generation MNS (Niobe, Stereotaxis) now allows complete, remote RF catheter ablation.

The Niobe MNS consists of two permanent neodymium-iron-boron magnets (inside fixed housings positioned on either side of the single-plane fluoroscopy table); their orientations relative to each other are computer controlled. While positioned in the “navigate” position, the magnets create a 360-degree omnidirectional rotation of the device by a uniform magnetic field (0.08 Tesla) within an approximately spherical navigation volume 20 cm in diameter (NaviSphere), sufficient to encompass the heart when the patient is properly positioned. The combination of rotation, translation, and tilt movements of the magnets adjusts the magnetic field to any desired orientation within the NaviSphere.

The mapping and ablation catheters are extremely flexible distally, especially the distal shaft of the catheter, and have three tiny magnets distributed along the distal shaft and tip of the catheter to increase responsiveness of the catheter to the magnetic field generated (eFig. 6.5). The catheter magnets align themselves with the direction of the externally controlled magnetic field to enable the catheter tip to be steered effectively. By changing the orientation of the outer magnets relative to each other, the orientation of the magnetic field changes, thereby leading to deflection of the catheter.

The system is integrated with a modified C-arm digital x-ray system, mainly a single-plane unit because of the physical limitations imposed by the magnets, although a biplane system can be installed and used when the magnets are stowed and not in use. Because of the magnets, the rotation of the imaging system is limited to an approximately 30-degree right anterior oblique view (RAO) and left anterior oblique

(LAO) in Niobe I and almost a 45-degree view with Niobe II. In the Niobe I iteration, the magnets can be swung only in (active navigation) or stowed, whereas in the Niobe II the magnets have a different housing and can also be tilted to allow for more angulation of the single-plane C-arm imaging system.

It is important to emphasize that the external magnetic field does not pull or push the tiny magnets and the catheters or guidewires in which they are contained. The position of the magnetic catheter within the heart is controlled by manual advancement or retraction of the catheter through a vascular sheath. A computer-controlled catheter advancer system (Cardiodrive unit, Stereotaxis) is used to allow truly remote catheter navigation without the need for manual manipulation. The operator is positioned in a separate control room, at a distance from the x-ray beam and the patient’s body. The graphic workstation (Navigant II, Stereotaxis), in conjunction with the Cardiodrive unit, allows precise orientation of the catheter by 1-degree increments and by 1-mm steps in advancement or retraction. The system is controlled by a joystick or mouse and allows remote control of the ablation catheter from inside the control room. In addition, the x-ray image data can be transferred from the x-ray system to the user interface of the MNS system to provide an anatomical reference.

Directional catheter navigation is accomplished by drawing a desired magnetic field vector on orthogonal fluoroscopic views with a digitization tablet (Fig. 6.24). A control computer then calculates the appropriate currents to each of the superconducting magnets. The resultant composite magnetic field interacts with the magnets in ablation catheter and deflects it to align parallel to the magnetic field. Magnetic field orientations corresponding to specific map points can be stored on the MNS and reapplied to return repeatedly and accurately to previously visited locations on the map. Navigation to a particular target often requires two or three manipulations of the magnetic field to refine the catheter position. Each magnetic field manipulation requires less than 5 seconds to activate. By changing the orientation of the outer magnets, the orientation of the magnetic field changes, thereby leading to the deflection of the catheter in parallel.

The MNS has become integrated with the CARTO RMT (Biosense Webster) electroanatomic mapping system. The CARTO RMT system is similar to the standard CARTO system but is able to localize the ablation catheter without interference from the magnetic field. CARTO RMT is able to send real-time catheter tip location and orientation

eFig. 6.5 Stereotaxis Catheters. Anteroposterior fluoroscopic view of the Stereotaxis remote magnetic (*RM*) catheter in the left atrium. Multipolar circular mapping, coronary sinus, and His bundle catheters are also shown. The RM catheter has a large distal mapping and ablation electrode; this and three other opaque regions more proximally on the catheter shaft contain magnetic elements that conform to changes in direction of an externally applied magnetic field. *PV*, Pulmonary vein.

Fig. 6.24 Stereotaxis Remote Magnetic Guidance System. *Top two central panels*, Representation of idealized left atrium shells with a green arrow (“vector”) that can be pointed in any direction with a computer mouse, commanding the magnetic steering mechanism to deflect the catheter tip in that direction. *Bottom two central panels*, Shell generated by electroanatomic mapping, integrated with the images on the Stereotaxis unit. These overlie the patient’s initial right anterior oblique and left anterior oblique fluoroscopic images. Tubular structures are the pulmonary veins and coronary sinus (pink). Other panels on the screen are various controls and indicators for the Stereotaxis manipulation.

data to the MNS. It also sends target locations, groups of points, and anatomical surface information from the electroanatomic map to the MNS.

The system has options for controlling deflectable ring (for PV mapping) and ICE catheters remotely, using a device into which the catheter handle is mounted and clamped. All functions (advancement/withdrawal; deflection in any direction; changing diameter of a ring catheter loop) are available via operator use of a joystick in the control room.

Technology Application

All the components of the MNS, as well as the x-ray, ablator, and stimulator, can be operated from the control room. Therefore, after initial placement of sheaths and catheters, the entire ablation procedure can be performed remotely from the control room. The Navigant system is the computerized graphical user interface system. It includes the software used for image integration and for control of the magnetic fields that orient the catheter within the heart, and allows the operator to direct the movement of the tip of the catheter to access the region of interest (see Fig. 6.24).

After synchronizing with respiratory and cardiac cycles, such as inspiration and the end-diastolic period, a pair of best-matched RAO-LAO images is transferred and kept in the Navigant screen as background references for orientation and navigation (see Fig. 6.24).

Thus the real-time catheter location information can be displayed on the Navigant reference x-ray images, thus enabling continuous real-time monitoring of the catheter tip position, even without acquiring a fresh x-ray image.

The operator can access an area of interest by using vector-based or target-based navigation. In vector-based navigation, the operator tells the system, by drawing a vector in virtual 3-D space on the computer, what orientation of the magnetic field is required. In target-based navigation, a target is placed on a specified point using the stored orthogonal fluoroscopic views; the user marks the support or base of the catheter (the distal portion of the sheath) on the pair of x-ray images. This provides Navigant with the data needed to compute field orientations corresponding to particular targets. Each time a vector is selected or a target is marked, the computer sends information to the magnets, which changes their relative orientation, and with it the orientation of the uniform magnetic field in the chest, so that catheter orientation is then changed within a few seconds (see Fig. 6.24). A target can also be defined by selecting a preset magnetic field vector based on a selected study protocol from the list on the Navigant. The software contains several preset vectors selected by the manufacturer, after careful appraisal of multiple CT images and reconstructions, for positioning the catheter at various anatomical landmarks. When a preset vector is applied, it can steer the catheter near the approximate region indicated. In addition, the software can be used to map various chambers

of the heart automatically. Once the tip electrode is at the desired location, the magnetic field keeps it in stable contact throughout the cardiac cycle; contact force (maximum 10 to 15 gm) is less than what can be applied with a manually directed catheter, but this is largely offset by the consistency of contact.

The magnetic catheter is advanced to target positions in the cardiac chamber of interest and guided by using the x-ray system, user interface monitors, and catheter advancer (Cardiodrive) system, which allows precise orientation of the catheter in extremely small increments (1-degree increments, by 1-mm steps) within the heart and vessels in advancement or retraction, thus making mapping more accurate. All vectors and targets selected can be saved, as can relative positions of the catheter advancer system, to allow specific areas in the heart or side branches of vessels to be revisited reproducibly.⁵⁶

CARTO RMT has also been integrated with the MNS and has been specifically redesigned to work in the magnetic environment of Stereotaxis. CARTO RMT includes all the latest updates such as CARTO-Merge, in which a 3-D reconstruction of a CT or MRI image can be integrated into the electroanatomic map. With the CARTO integration, communication between the two systems allows for real-time catheter orientation and positioning data to be sent from CARTO to the Stereotaxis system, and for the catheter tip to be displayed on the saved images stored on the Navigant system. This permits tracking of the ablation catheter without having to update the radiographic image as often. Magnetic vectors can also be applied from the CARTO screen. A feature called “design line” can be used to send a line of points, either for mapping a specific area or potentially as a line of ablation points. “Click and go” is a tool allowing for an area of the map to be clicked on to set a target and have the system guide the catheter to this point. Because Stereotaxis and CARTO have feedback integration, the CARTO system can feed back to the Stereotaxis system if the exact point is not reached, thus allowing for further automatic compensation by the software until the desired point is reached. The combined system has the capability of automatically mapping chambers (anatomy and activation times) by using predetermined scripts. The accuracy of such automaps is highly dependent on the anatomy, as well as where in the heart the operator designates the starting point for mapping. At present, standard 4- and 8-mm-tip and irrigated 3.5-mm-tip RF catheters are available.

Clinical Implications

Precise target localization and catheter stability are prerequisites for successful RF applications and to minimize risks of potential complications. Stiff, manually deflectable catheters with a unidirectional or bidirectional deflection radius, which deflect in a single plane, have several inherent limitations because stable electrode-tissue contact can be difficult to achieve, particularly in regions of complex cardiac anatomy. This is much less problematic using the MNS. For example, in repaired congenital heart disease, such as Mustard procedures, the pulmonary venous atrium can be accessed retrogradely (via the aorta), obviating the need for baffle puncture. Another strength of the current MNS lies in the precision of catheter movement and the ability to steer the flexible distal portion of the catheter in any direction in 3-D space.

The MNS has been used for ablation of AVNRT, BTs, AFL, idiopathic and scar-related VT, and especially AF.⁵⁷ Intracardiac electrograms and stimulation thresholds are not significantly different from those recorded with a standard, manually deflected ablation catheter, and the safety of standard EP procedures has not been compromised by use of the MNS.^{56,58} For AF ablation, efficacy outcomes were accomplished with use of MNS when compared with conventional manual navigation. MNS was associated with significant reduction of fluoroscopy time but a slightly longer total procedure time.^{59,60} Because of the flexibility of the catheters, cardiac perforation is extremely unlikely.

Although the current MNS may not offer a distinct advantage over conventional catheters for navigation to targets that are easily reached, it has potential advantages for complex catheter maneuvers and navigation to sites that are exceptionally difficult to reach with a standard catheter. In addition, catheter mobility and endocardial stability can be superior by virtue of the compliance of the distal catheter and lack of constraints on the magnetic vector used to steer the catheter. Cardiac and respiratory motion can be buffered by the catheter compliance, thereby contributing to endocardial contact stability.

After the diagnostic catheters are positioned, the EP study and ablation process can be performed completely from inside the control room. This offers several potential advantages, including reducing fluoroscopic exposure time for the operator, reducing the strain from standing next to the bed for long periods while wearing a lead apron, and facilitating simultaneous catheter navigation and electrogram analysis.

A unique feature of the current MNS is that the magnetic vector coordinates used to navigate the magnetic catheter to a particular site can be stored and reused later in the study to return to a site of interest. The integration of a stable magnetic catheter with the CARTO electroanatomic mapping system is useful to reconstruct an accurate electroanatomic map by acquiring many more points than are possible manually for successful ablation, even of challenging areas.

For certain procedures, notably AF ablation, MNS can decrease fluoroscopy time significantly. Although the use of MNS may increase total procedure duration, procedure times decrease with increasing operator experience.

Limitations

A potential limitation of the MNS is the interference induced by the magnetic field in the surface ECG. The origin of the induced potentials is thought to be attributable to blood flow within the magnetic field. Blood is an electrolyte solution that can induce the potential because of motion within the magnetic field. The magnetic field strength used for catheter manipulation is approximately one order of magnitude less than that associated with MRI. The interaction of the magnetic field with the surface ECG is therefore less in magnitude compared with MRI and is restricted to the ST segment, and the temporal distribution of the interfering signal component probably would not compromise cardiac rhythm analysis or analysis of the P wave or QRS morphology. However, the interpretation of changes in the ST segment would be predictably compromised by this interference. Whether this distortion will affect arrhythmia analysis is currently being investigated.

Claustrophobia and morbid obesity are contraindications for using the MNS because of the restricted space within the system; deep sedation or anesthesia obviate this problem. The next generation of the MNS features an open design that is more comfortable for obese patients and those with claustrophobia. Patients with pacemakers or defibrillators had been excluded because of possible electromagnetic interference, although few problems have been observed, even with very old devices. In addition, the MNS requires monitoring instruments that are compatible with magnetic fields.

The angulation of the fluoroscopic system is limited to 30 degrees to 45 degrees for both LAO and RAO projections when the magnets are in the “navigate” position. Although this may not be important in simple ablations, addressing more complex substrates can be more challenging.

The MNS is an evolving technology. Further technical development through the availability of additional catheter designs (e.g., number of recording electrodes) is necessary to address more complex arrhythmias in the future.

The use of the MNS for ablation of AF, MRAT, and typical AFL was associated with slightly longer procedure times as compared with

conventional catheter navigation. The preparation for the procedure (registration and positioning of the magnets for MNS) is still time-consuming. Furthermore, the use of the MNS for catheter ablation of typical AFL resulted in a lower overall success rate (achievement of cavotricuspid isthmus block and freedom from AFL recurrence during follow-up). A lower success rate of PV electrical isolation was also observed when a standard 4-mm-tip ablation catheter was used. Some reports also expressed concern about a higher incidence of char formation during MNS-guided ablation of AF and AFL using solid tip catheters. Irrigated magnetic catheters are now used and appear to the risk of char formation, and increase lesion efficacy during MNS-guided ablation.

SENSEI ROBOTIC NAVIGATION SYSTEM

Fundamental Concepts

The Sensei robotic navigation system (Hansen Medical) is an electro-mechanical system that realizes catheter navigation by two concentric steerable sheaths (Artisan, Hansen Medical) incorporating an ablation catheter. The outer sheath (14 Fr) and the inner sheath (10.5 Fr) are both manipulated via a pull-wire mechanism by a sheath-carrying robotic arm that is fixed at the foot of the patient's table. The robot arm obeys the commands of the central workstation (master console) positioned in the control room.⁶¹

Catheter navigation is realized using a 3-D joystick (Instinctive Motion Control, Hansen Medical) and allows a broad range of motion in virtually any direction. At the master console, fluoroscopic images, ICE images, and other 3-D representations (electroanatomic maps) are displayed, providing immediate feedback to the operator. Seamless instinctive integration and interpreted motion logic allow the physician to direct catheter movement in 3-D regardless of image orientation or perspective. To provide a representation of tactile feedback, the system continuously monitors the contact force that is exerted by the catheter tip by using a specially designed algorithm (IntelliSense, Hansen Medical). If the contact force exceeds a preset limit, an optical alarm is displayed, and catheter advancement is rendered virtually impossible.

In general, all catheters and all electroanatomic mapping systems may be used. Apart from the different navigational approach, the technical aspects of the ablation are identical to the manual ones. Integration of this robotic system with available mapping systems (CARTO and EnSite NavX) is feasible.

Technology Application

Both the inner and the outer sheaths should be flushed with heparinized normal saline before insertion and continuously throughout the procedure to prevent clot formation and air embolism. The steerable guide sheath is manually inserted via a 14 Fr sheath in the right femoral vein and advanced manually into the inferior RA under fluoroscopy guidance. To minimize the risk of vascular complications, it is advisable to obtain venous access under ultrasound guidance, initially insert an 8 Fr sheath and upsize to 11 Fr and then 14 Fr, and then insert a long, 30-cm 14 Fr sheath that usually ends at the level of the liver. Through this, the steerable sheath is inserted with the ablation catheter leading by at least 10 cm into the RA. At this level, the ablation catheter is withdrawn into the steerable sheath with only the distal electrodes protruding. Failure to leave the ablation catheter out beyond the end of the Artisan sheath and to observe the catheter system advance up to the RA increases the risk of vascular injury.

Subsequently, the position of the sheath is registered into the robotic catheter remote control system. The registration process involves the use of two orthogonal fluoroscopic views of the heart (anteroposterior

and lateral) to allow saving the position of the guide sheath in 3-D space. Following registration, the remote control system is used to steer the tip of the ablation catheter to the desired targets; all four cardiac chambers are accessible.

For ablation in the LA, transseptal puncture is usually performed manually with a standard transseptal sheath and needle system. If a second atrial septal puncture is required, the guidewire or EP catheter placed in the LA through the first transseptal puncture is used as a marker, and the second transseptal puncture is performed with the Sensei system. A custom-made transseptal needle (Hansen Medical) is advanced through a transseptal sheath and dilator (Hansen Medical) under fluoroscopy and ICE guidance. After the septum is punctured, the steerable guide sheath and dilator are advanced robotically in the LA, and the dilator is replaced with the ablation catheter, which is then inserted into the guide sheath with approximately 1 cm of the ablation catheter exposed from the tip of the guide sheath.⁶¹

The steerable sheath containing the ablation catheter is remotely controlled by a physician at the master console. Manipulation of other catheters, including the circular mapping catheter, however, is performed manually by a second operator at the procedure tableside.

The required amount of energy applied during remote navigation cases is generally lower than that of manual cases, likely because of enhanced catheter contact and stability throughout the cardiac cycle afforded by the robotic sheath. As a result, the rate of steam pop and potential thermal complications may be higher if compensatory energy-lowering strategies are not implemented.

Clinical Implications

Endocardial navigation using conventional manual steerable diagnostic and ablation catheters can be challenging and time-consuming, and require certain skills and experience. The robotic catheter remote control system was designed to facilitate control and allow precise and stable positioning of catheters within the cardiovascular system. This technology has the potential to overcome some of the limitations of manual control by combining the ease of navigation with a readily available wide navigational field.⁶²

An additional advantage of remote navigation is the ability to reduce the operator's radiation exposure because of the remote location of the workstation from the fluoroscopy unit. Furthermore, because of better catheter stability and easier navigation with the robotic system, total fluoroscopy time and patient and staff radiation exposure can potentially be reduced; however, this remains to be determined.⁶¹

Several studies have shown that robotic navigation and ablation of AF are as safe and effective as manual ablation. Furthermore, the use of the robotic catheter remote control system for transseptal puncture and endocardial navigation is safe and feasible. However, its usefulness in decreasing procedure time and improving procedural efficacy and safety compared with current approaches (which continue to evolve) requires further evaluation in randomized clinical trials. In addition, a comparison between this technology and remote magnetic navigation may be warranted.

In contrast to the magnetic guidance system (Niobe, Stereotaxis), which requires specific compatible magnetic-guided catheters, the Sensei robotic navigation system is an open platform system whereby almost any mapping or ablation catheter of appropriate size can be introduced into the remotely steerable catheter or sheath. In addition, the MNS requires continuous alteration and adjustment of the magnetic field and then advancement of the catheter in that direction. With the use of the Sensei robotic navigation system, a continuous uninterrupted motion of the ablation catheter can be achieved with the use of the instinctive motion controller. Finally, the Sensei robotic system is, at least in principle, portable and could be transported from one

laboratory to another in the facility, whereas the remote MNS requires large magnets permanently installed in one location.^{61,62}

Limitations

Although the remote location of the workstation from the fluoroscopy can significantly reduce radiation exposure to the physician, there is a need for a second physician or operator to manipulate the circular mapping catheter at the bedside during a PV isolation procedure. Radiation exposure is not reduced to this operator or to the patient. With the use of other AF ablation strategies, such as anatomically based ablation, however, there would be no need for a separate mapping catheter. In the future, it is possible that both the ablation and mapping catheters will be controlled in tandem with two coordinated robotic steerable guides, though likely at increased procedural cost.

The steerable robotic sheath is inherently stiff to make it pushable and mechanically steerable, and it must be advanced through a 14 Fr vascular sheath. The size of the introducer sheath itself increases the likelihood of complications, and advancing the steerable sheath into the vein may cause dissection. The amount of force required to advance the Artisan through the hemostatic valve of the sheath at the groin is significant. Therefore insertion of the 14 Fr sheath and the Artisan catheter does require special care to avoid retroperitoneal vascular complications.

Infrequent cases of cardiac perforations and PV stenosis were reported in several studies using the Sensei robotic navigation system for catheter ablation of AF. Some of those events were thought to be consequent to the use of high power output during RF ablation. Therefore it is important to recognize that with better catheter contact and stability offered by the robotic sheath, the effectiveness of ablation is increased, and less power is probably needed to achieve adequate attenuation of electrograms. Further studies will be required to evaluate adequate and optimal tissue contact during navigation mapping and ablation, as well as the optimal ablation energy parameters while using a robotic system at different pressure levels, and compare those with the parameters used with conventional manually operated catheters.

During catheter ablation of AF, the major advantage of robotic navigation with respect to stability as compared with manual navigation is along the LA roof. However, at the anterior inferior portion along the lateral circumferential ablation line, catheter stability is suboptimal in almost 50% of the cases despite robotic navigation. This may be explained by the fact that this is the most distant location from the transeptal puncture site. This limitation can be partially compensated for by a “deeper” LA position of the outer sheath and the application of a distal bend. In addition, electrical isolation of the right inferior PV is challenging using this system. Because of the large outer diameter of the sheath, robotic navigation to the distal CS is discouraged. This may limit its use in ablation procedures for long-lasting persistent AF or perimitral LA macroentrant tachycardias, which frequently require epicardial ablation via the CS.

Certain ablation catheters with flat wire deflection mechanisms are not compatible with the Sensei robotic navigation system. The flat wire mechanism allows the catheter to only bend along a 2-D plane described by the flat surface of the wire without causing tension. When the robotic sheath moves in a direction that is not along the 2-D plane of the flat wire, tension is created, resulting in an uncontrolled rebound rapid correction of the system, which can potentially cause cardiac perforation. This rarely happens with manual manipulation of the catheter alone because the operator rotates the catheter appropriately to achieve the desired position.

Although the robotic system affords greater stability at ablation targets, complications that occur with the manual approach can also occur with the robotic system. Given the stability of the system and

also the stiffness and rigidity of the sheath, it is crucial that the operator understands the anatomy of the LA and adjacent structures. Even more so with the robotic navigation system, it is very important that the operator is cognizant of possible complications and is able to manage such complications effectively.

MEDIGUIDE NAVIGATION SYSTEM

Fundamental Concepts

The guided medical positioning system (MediGuide Technology, St. Jude Medical, St. Paul, MN, United States) is a novel nonfluoroscopic, sensor-based electromagnetic catheter visualization system. This technology enables real-time tracking of the catheter tip that is displayed on a prerecorded cine loop and is constantly visible during the procedure.^{63,64}

The MediGuide technology consists of three components: (1) a transmitter generating a 3-D electromagnetic field (installed within the fluoroscopy detector of a conventional flat panel x-ray imaging system); (2) a miniaturized (less than 1 mm³) single coil sensor (MediGuide Enabled Livewire, St. Jude Medical) embedded within an intracardiac device such as a conventional EP or ablation catheters, sheaths, and wires; and (3) a magnetic field reference sensor attached to the patient's chest (which functions as an anchor for the system and continuously scans patient position within the tracking space).^{63,64}

MediGuide combines the x-ray system with electromagnetic tracking on the hardware level. The transmitter unit is installed within the fluoroscopy detector of a conventional x-ray imaging system. This assembly enables aligning the fluoroscopic and electromagnetic 3-D working spaces and allows for the auto-registration of sensor tracking into dynamic x-ray imaging. As a result, the sensor-equipped EP catheter can be either visualized on fluoroscopy or tracked nonfluoroscopically at the identical position by the electromagnetic sensor field (Fig. 6.25). The use of prerecorded cine loops instead of live fluoroscopy allows for nonfluoroscopic tracking of catheters within the x-ray environment and helps reduce radiation exposure. The speed of the cine loop is matched to the real-time ECG signal to adjust for cardiac cycle dependent changes in catheter position. Furthermore, the reference sensor attached to the patient's chest helps compensate for respiration and for movement of the patient or the table, as well as changes in C-arm angulation.^{63–65}

Technology Application

Initially, before EP catheter introduction, two cine loops with a length of three cardiac cycles are recorded in standard RAO 30-degree and LAO 60-degree projections. A simultaneous display of these two pre-acquired cine loops in a continuous pseudo-biplane mode constitutes the background for the nonfluoroscopic placement of the sensor-equipped diagnostic and ablation catheters. Contrast-enhanced background angiograms (e.g., LA or PV angiography), as opposed to native cine loops, further enhances orientation within complex anatomies (Fig. 6.26). The sensor-enabled catheters then are positioned into the appropriate cardiac chambers using MediGuide for nonfluoroscopic catheter tracking within prerecorded cine loops.

MediGuide technology can be used in conjunction with the EnSite NavX electroanatomic mapping system (see Fig. 6.26). One of the sensor-equipped catheters can be used to acquire the electroanatomic map. The use of MediGuide data improves impedance-based field adjustment (“field scaling”) of the EnSite NavX system, resulting in more realistic chamber reconstructions. Furthermore, using the sensor-equipped catheters as the positional reference for the EnSite system allows for the detection and correction of reference catheter dislocations, thereby preventing catheter shifts, which necessitate repeated reconstruction and registration processes.^{63–65}

Fig. 6.25 MediGuide-Enabled Catheter Visualization. Two decapolar diagnostic catheters are visualized by both the MediGuide system (green and yellow tip) and real-time fluoroscopy (right anterior oblique [RAO] and left anterior oblique [LAO] views). In addition, different landmarks are set: ostium of the superior vena cava (1), ostium of the inferior vena cava (2), tip of the coronary (CS) catheter (3), ostium of the CS (4), and fossa ovalis (5). (From Sommer P, Wojdyla-Hordynska A, Rolf S, et al. Initial experience in ablation of typical atrial flutter using a novel three-dimensional catheter tracking system. *Europace*. 2013;15:578–581.)

Clinical Implications

The MediGuide tracking platform enables excellent 3-D orientation for spatial catheter positioning based on underlying prerecorded cine loops. This system can be used as a “stand-alone system” for simple catheter ablations, such as AVNRT, BT, and CTI ablation, where it can potentially allow almost complete nonfluoroscopic procedures, except the acquisition of the two cine loops that can be taken prior catheter insertion (see Fig. 6.25). This catheter tracking technology can also be combined with a 3-D electroanatomic mapping system for more complex ablations (e.g., AF; see Fig. 6.26). The option to use contrast-enhanced background angiograms further improves catheter visualization in relation to cardiac anatomy.

Initial studies using MediGuide demonstrated significant (more than 50%) reduction of radiation exposure to both the patient and the operator, which was found to be its most prominent measurable benefit. These effects were achieved with minor adaptations of established workflows and without excessive procedure duration or complication rates.

Limitations

One of the limitations of the MediGuide system is that catheter shaft and transseptal sheaths are not visualized on MediGuide screens. Therefore additional fluoroscopy can be required when catheter orientation is not entirely clear. Also, fluoroscopy is required during manipulation of EP catheter lacking the magnetic sensors and during atrial septal puncture. Another limitation is the limited selection of EP catheters being equipped with MediGuide sensor technology. A broader variety of sensor-equipped catheters in addition to sensor markers on the transseptal sheath would offer a greater variability in the application of this technology.

BODY SURFACE POTENTIAL MAPPING

Fundamental Concepts

Although the conventional 12-lead ECG is extensively used, its limitations for optimal detection of cardiac abnormalities are widely appreciated. The main deficiency in the 12-lead approach is that only six chest

electrodes are incorporated, and they cover a relatively constrained area of the precordium. The main reason for the choice of the location of the conventional precordial electrodes, suggested by Wilson in the 1940s, was the need to adopt some standard, which to this day has remained relatively unchallenged. In the years since then, the growing appreciation for the limitations of the conventional precordial electrode positions and the increase in understanding of the localization of various cardiac abnormalities on the body surface have led to the suggestion of various alternatives.

One of the most widely studied alternatives to the 12-lead ECG in clinical and experimental electrocardiology has been body surface potential mapping (BSPM). In this approach, 32 to 256 electrodes are used in an attempt to sample all ECG information as projected onto the body's surface. The merits of this enhanced spatial sampling are obvious, in that localized abnormalities that may be difficult to detect using the 12-lead approach can readily be picked up with the additional electrodes.⁶⁶

BSPM is defined as the temporal sequence of potential distributions observed on the thorax throughout one or more electrical cardiac cycles. BSPM is an extension of the conventional ECG aimed at refining the noninvasive characterization and use of cardiac-generated potentials. The improved characterization is accomplished by increased spatial sampling of the body surface ECG, recorded as tens or even hundreds of unipolar ECGs, simultaneously or individually, with subsequent time alignment.

BSPMs provide much more electrical and diagnostic information than the 12-lead ECG. They contain all the electrical information that can be obtained from the surface of the body, and they reveal diagnostically significant electrical features in areas that are not sampled by the 12-lead ECG systems. In addition, BSPMs often show distinct electrical manifestations of two or more events simultaneously evolving in the heart; they make it possible to compute any ECG that would be obtained from any pair or combination of body surface electrodes (i.e., from any current or future lead system). In addition, the recorded data can be displayed as a sequence of contour maps, thus allowing for the isolation of significant ECG events in both space and time.

BSPMs can be used to reconstruct epicardial and, in some cases, endocardial potential distributions, excitation times, and electrograms

Fig. 6.26 Nonfluoroscopic Tracking of the MediGuide-Enabled Ablation Catheter During Circumferential Left Pulmonary Vein (PV) Isolation. Snapshots show MediGuide screens (A and C) with PV angiographic background loop, three-dimensional MediGuide technology markers (SVC, IVC CS, PV ostia, and oval fossa), and sensor icons of diagnostic catheter (yellow) and ablation catheter (red). Respective Ensite NavX screens are also displayed (B and D). CS, Coronary sinus; IVC, inferior vena cava; LAA, left atrial appendage; LAO, left anterior oblique views; LIPV, left inferior PV; LSPV, left superior PV; RAO, right anterior oblique; RIPV, right inferior PV; RSPV, right superior PV; SVC, superior vena cava. (From Rolf S, et al. Catheter ablation of atrial fibrillation supported by novel nonfluoroscopic 4D navigation technology. *Heart Rhythm*. 2013;10: 1293–1300.)

noninvasively, by means of inverse procedures, which help transform the ECG into an imaging method of electrical activity. This yields 3-D images that depict anatomical features with superimposed activation isochrones or excitation and recovery potentials, isochrones, and electrograms.

In BSPM measurements, unipolar potentials of single heartbeats are acquired simultaneously at more than 60 locations covering the whole thorax. A Wilson central terminal is used as a reference for the unipolar leads. Lead sites in the array are arranged in columns and rows, and the electrodes are attached to flexible plastic strips, attached to dozens of thoracic sites vertically, with the highest electrode density

at the left anterior thorax. Recordings are band pass-filtered at 0.16 to 300 Hz and digitized with a sampling frequency of 1 kHz.

BSPMs depict the spatial distribution of heart potentials on the surface of the torso. Initially, all lead tracings are visually screened to reject poor-quality signals. The amplitude of every electrogram is measured at a given time instant during the cardiac cycle and plotted on a chart representing the torso surface. Several analytical procedures are used to convert the grid of data points into map contours. The time interval between successive instantaneous maps (frames) is generally 1 to 2 milliseconds. A sequence of 400 to 800 frames shows the evolution of the potential pattern during the cardiac cycle. Often 20 to 50

Fig. 6.27 Body Surface Potential Mapping. Body surface potential distribution at the peak of the R-wave during sinus rhythm. Potentials are displayed on a realistic human torso model with anterior (*left*) and posterior (*right*) views. Positive potentials are represented in red and negative in blue. (From Bear L, Cuculich PS, Bernus O, Efimov I, Dubois R. Introduction to noninvasive cardiac mapping. *Card Electrophysiol Clin.* 2015;7:1–16.)

properly selected maps are sufficient to show the essential features of the time-varying surface field.

Localization of the site of origin of focal tachycardia, pacing site, or myocardial insertion site of a BT relates to the thoracic site of greatest negativity in the isointegral map. An activation wavefront moving away from such sites yields a negative body surface identifier because of the dominant effect of activating the remainder of the myocardial mass away from the stimulus site (Fig. 6.27).

Clinical Implications

BSPM has been used in both experimental and clinical setting for the detection and diagnosis of various pathological conditions. BSPM has been used for patients with conditions such as pulmonary embolism, aortic dissection, and acute coronary syndromes. It has also been used for diagnosing an old myocardial infarction (MI), recognizing ventricular hypertrophy, and ascertaining the location, size, and severity of MI and the effects of different interventions designed to reduce the infarct size.⁶⁶

From an EP standpoint, BSPM has been studied for the discrimination of clockwise and counterclockwise AFL, localization of the earliest retrograde atrial activation site in dogs with simulated Wolff-Parkinson-White syndrome and orthodromic AVRT, localization of the ventricular insertion site of BTs during preexcitation, localization of sites of origin of ATs and VTs, and localization of endocardial or epicardial pacing sites.

Many studies have demonstrated higher diagnostic and prognostic value of BSPM as compared with the 12-lead ECG; nonetheless, BSPM has not been adopted in clinical practice. Although ongoing research continues to address the role of BSPM, and how BSPM addresses many of the inadequacies associated with the conventional 12-lead ECG approach, the clinical effectiveness of this procedure has not been established and the incremental value of BSPM over traditional 12-lead ECG have not justified the additional procedural complexity and expense. Hence, BSPM is mostly used as a research tool, rather than a routine diagnostic method because of significant limitations.^{66,67}

Limitations

The ability to determine precise details of cardiac electrical activity from BSPM is limited by the filtering effects of the torso cavity—that

is, body surface potentials are a smoothed representation of the underlying global cardiac electrical activity. A second limitation of BSPM is the complexity of the recording, which requires many leads from each patient, sophisticated instrumentation, and dedicated personnel. Complexity of the interpretation is another limitation because it is mostly based on pattern recognition and knowledge of variability in normal subjects and in patients—features that are difficult to memorize. Therefore, visual inspection and measurement of BSPMs cannot result, *per se*, in direct localization of single or multiple electrical events as they occur in the heart. Furthermore, BSPMs do not offer a picture of the heart, but they show an attenuated and distorted projection of epicardial and intracardiac events on the body surface. In addition, the method of interpolating maps from acquired data is vulnerable to the precision of localization of the electrode sites and to the assurance that each electrode is receiving a true signal.^{66,67}

ELECTROCARDIOGRAPHIC MAPPING

Fundamental Concepts

Body surface electrocardiographic imaging (ECGI), also called electrocardiographic mapping (ECM), is a noninvasive technique providing global electroanatomic maps of cardiac chambers by projecting body surface potentials onto the cardiac epicardial geometry derived from a thoracic CT scan or MRI.⁶⁸

The ECM system has three main components: a multielectrode ECG vest, a multichannel mapping system for ECG signal acquisition, and an anatomical imaging modality to determine the heart-torso geometry.⁶⁹ ECM requires two sets of data: ECG unipolar potentials measured over the body surface and the heart-torso geometrical relationship relating the epicardial surface to the location of the recording body surface ECG electrodes. The body surface ECG unipolar potentials are measured using a 252-electrode ECG vest (Fig. 6.28). With the vest remaining in the same position, the precise anatomic relation between the cardiac geometry and the torso electrodes is determined using noncontrast thoracic CT. The electrode positions and 3-D epicardial geometry are obtained via segmentation from the CT images.^{69,70}

Using mathematical algorithms (the inverse problem of electrocardiography), the ECM noninvasively computes and reconstructs 1500 epicardial unipolar electrograms from measured torso potentials for each beat per cycle. This is achieved by solving the inverse solution to Laplace's equation (the forward problem computes body surface potentials from epicardial potentials). Laplace's equation describes the electric potential field in the volume between the heart surface and the body surface. Accordingly, when one 3-D surface of known geometry is placed within another of known geometry, if the electrical potential on one surface is known, the potential on the other can be calculated. Because the 3-D geometry of the torso and that of the epicardial surface of the heart can be reconstructed from segmental CT images, and body surface unipolar potentials are recorded by the ECG vest (the relative positions of body surface electrodes can be visualized on the torso geometry), unipolar potentials on the cardiac epicardium can be computed. The inverse solution to Laplace's equation using the boundary element method predicts how a remotely detected signal by the ECG vest would have appeared at its source, the epicardial surface, so that electrograms are reconstructed at epicardial sites in the absence of physical electrode contact at those locations (virtual electrograms). Importantly, the inverse problem is ill-posed—that is, small errors in the input data (noise on the ECGs, inaccurate electrode locations, and inaccurate conductivity values)—can cause large errors in the solution. Therefore ECGI employs regularization techniques that impose physiologically based constraints or iterative schemes to stabilize the solution in the presence of these inaccuracies.^{70,71–73}

Fig. 6.28 Electrocardiographic Mapping (ECM) Procedure. Body surface potential mapping (BSPM) is recorded using a multichannel (256-electrode) mapping system embedded in a vest that can easily be placed on a patient torso. Noncontrast computed tomographic (CT) scan of the chest is performed with the body surface electrodes applied simultaneously to record the precise anatomic relation between the 252 electrodes on the vest (shining dots in CT images) and the geometry of the epicardial surface of the heart. By combining the BSPM and heart-torso geometry information, ECM reconstructs 1500 unipolar electrograms from the 252 electrodes. Out of these 1500 unipolar electrograms, isopotential, isochronal, and voltage maps can then be reconstructed. EGM, Electrogram. (From Cakulev I, Sahadevan J, Arruda M, et al. Confirmation of novel noninvasive high-density electrocardiographic mapping with electrophysiology study: implications for therapy. *Circ Arrhythm Electrophysiol.* 2013;6:68–75.)

Once the potential field has been established, more than 1500 activation points can be displayed as computed electrograms or as color-coded isopotential maps for each heartbeat. The activation time at each epicardial site is determined by taking the time instant with maximum negative time derivative ($-dV/dt$) on the virtual unipolar electrogram, allowing the generation of activation sequences (isochronal maps). Activation movies (propagation maps) can be constructed by animating the activation wavefront on the patient-specific CT-derived epicardial surface. The reconstruction is performed during a single beat and does not require accumulating data from many beats.^{66,70,72–76}

It is important to understand that ECGI is not BSPM. BSPM is only an extension of the body surface 12-lead ECG, accomplished through the application of a large number of electrodes to the torso surface. The output of BSPM is potentials on the body surface, not on the heart.

In contrast, ECGI overcomes some of the limitations of BSPM by solving the “electrocardiographic inverse problem” to estimate the equivalent cardiac sources from body surface potentials, which then are projected onto the cardiac epicardial geometry.^{67,74}

Technology Application

ECM can be performed preprocedurally or periprocedurally. The 252-electrode vest is fitted to the patient’s torso, and recording of the arrhythmia is acquired. In patients with infrequent or intermittent arrhythmias (e.g., PVCs or PACs, paroxysmal AF with focal triggers), patients may be allowed to ambulate, and the vest can be applied for several hours to help capture the culprit arrhythmia.⁷⁷

Once the index arrhythmia is recorded, the exact geometry of the epicardial and torso surfaces and vest electrode positions is obtained

by anatomical imaging modalities, such as noncontrast thoracic CT or MRI. Scans are usually set to an axial resolution between 0.6 and 1 mm and are typically gated at the R wave of the ECG to obtain diastolic volume (geometry for reconstruction of activation). Systolic volume, gated during the T wave of the ECG, is also measured to obtain suitable geometry for reconstruction during the repolarization phase. The transverse slices are segmented slice by slice to obtain heart geometry (as epicardial contours on each slice) and torso geometry (described by body surface electrode positions, seen as bright dots on the images; see Fig. 6.28). The geometry of the heart and torso surfaces is then assembled in a common x - y - z coordinate system to provide the geometrical heart-torso relationship.

ECM reconstructs an epicardial electroanatomic map noninvasively by combining a 252-electrode body surface ECG with a CT scan of the heart-torso geometry. The ECM images can be presented as 3-D color-coded, epicardial isopotential, isochronal, propagation, and voltage maps. Characteristics of activation can be analyzed at any point in the cardiac cycle, and atrial and ventricular patterns can be displayed.⁶⁸

Four modes of display are typically used. Epicardial potential maps depict the spatial distributions of potentials on the epicardium (see Fig. 6.28). Each map depicts one instant of time; maps are computed at 1-millisecond intervals during the entire cardiac cycle. The electrograms depict the variation of potential with respect to time at a single point on the epicardium. The electrograms are computed at many points (more than 1500 sites) around the epicardium. In isopotential maps, activation is assumed to occur when the electrogram voltage reaches a predefined magnitude and can be displayed as a moving image over the surface (eFig. 6.6). Isochrone maps depict the sequence of epicardial activation based on local activation time, taken as the point of maximum negative derivative ($-dV/dt_{\max}$) of the QRS segment in each electrogram (Fig. 6.29). Recovery times are assigned as the point of maximum derivative (dV/dt_{\max}) of the T wave segment. Activation times are determined as the time of maximum negative derivative in the epicardial electrograms. Information from neighboring electrograms is used to edit activation times in electrograms with multiple large negative derivatives.

Lines of block are drawn to separate sites with activation time differences more than 30 milliseconds.

Clinical Implications

Noninvasive diagnosis of arrhythmias is currently based on the standard 12-lead ECG, BSPMs, or paced body surface QRS integral mapping. Standard diagnostic techniques such as the ECG provide only low-resolution projections of cardiac electrical activity on the body surface and cannot provide detailed information on regional electrical activity in the heart, such as the origin of arrhythmogenic activity, sequence of arrhythmic activation, or existence and location of an abnormal EP substrate. Recently ECM (ECVUE, CardioInsight Technologies, Cleveland, OH, United States) has emerged as a tool of substantially greater clinical value than the 12-lead ECG in the diagnostic and therapeutic management of cardiac rhythm disorders.⁷⁸

ECGI has been investigated in experimental and clinical studies in normal cardiac EP and various atrial and ventricular arrhythmias, ventricular conduction abnormalities, as well as repolarization disorders. Several studies demonstrated the value of ECM for diagnosing the mechanism of arrhythmia (focal vs. macroreentrant), identifying the chamber of interest, localizing the origin of focal AT and VT (see eFig. 6.6 and Fig. 6.29; see eFig. 11.1), and evaluating the arrhythmogenic substrate (e.g., low voltage and fractionated electrograms in post MI scar). Such information can provide necessary guidance to facilitate planning management strategies, including EP testing and catheter ablation.^{69,72–74,77,79}

ECGI is capable of recording and displaying global electrical activation of any single beat and, unlike invasive contact electroanatomic mapping systems, does not require accumulating data from many beats. This property is particularly useful in patients with PACs or PVCs that are not of sufficient frequency to allow sequential mapping. This also allows for prolonged bedside noninvasive monitoring in patients with transient events or scarcely inducible arrhythmias and those with multiple arrhythmias. In addition, in patients with paroxysmal AF, identification, and localization of triggering PACs can potentially identify

Fig. 6.29 Electrocardiographic Mapping (ECM) of Focal Atrial Tachycardia. The PVC QRS morphology suggests an origin from the right ventricular outflow tract (RVOT). (B) Two ECM isopotential maps show the propagation of the depolarizing wavefront. The first panel on the left shows the location of the earliest activation (*white color*) of the PVC in the vicinity of the proximal left anterior descending (LAD) coronary artery, but on the left side of the ventricular septum. The electrograms with a QS complex morphology (shown in both panels of [B] on the right side of each ECM) indicate an epicardial origin. The electrograms around, but not at, the focus, lack the sharp negative deflection of the focal electrogram, and exhibit more slurring of the downslope. The vertical lines across the electrograms show the time point at which the potential was measured. Ao, Aorta; LV, left ventricle; MA, mitral annulus; PA, posteroanterior. (From Yamashita S, Sacher F, Mahida S, et al. Role of high-resolution image integration to visualize left phrenic nerve and coronary arteries during epicardial ventricular tachycardia ablation. *Circ Arrhythm Electrophysiol*. 2015;8:371–380.)

important targets for ablation. However, the impact of ECM on the success, safety, and efficiency of the subsequent ablation procedure remains to be evaluated.^{68,74–76,80–82}

Noninvasive mapping has demonstrated the ability to image arrhythmogenic substrate having EP characteristics of low voltage, electrogram fragmentation, and presence of late potentials. In addition, ECM can potentially image the reentry pathway and its key components in atrial and ventricular macroreentrant tachycardias, including the critical isthmus, its entry and exit sites, lines of block, and regions of slow and fast conduction. Although clinical reentry usually occurs in the endocardium, the subepicardium plays an important role in the maintenance of reentry in a small proportion of patients undergoing ablation therapy. Interpretation of intramural arrhythmogenic activity can be further enhanced by direct catheter mapping or noncontact catheter reconstruction of EP information on the endocardial surface simultaneously with noninvasive epicardial ECM. The combination of epicardial and endocardial EP information, with knowledge of the intramural anatomical organization of the myocardium, can provide an unprecedented ability to localize arrhythmogenic activity within the myocardial depth by using only noninvasive or minimally invasive procedures.^{76,77,83}

ECGI can possibly be used to quantify ventricular dyssynchrony, identify potential responders/nonresponders to cardiac resynchronization therapy, and guide electrode placement for effective resynchronization therapy. Furthermore, ECGI's ability to noninvasively image regions of dispersion of repolarization in the form of QRST integral maps (or other metrics of repolarization dispersion) during a single beat provides a feasible and computationally efficient method for evaluating the severity of the substrate in patients at risk of developing arrhythmias. Noninvasive reconstruction of epicardial measures of repolarization dispersion can therefore provide a tool for rapid screening of patients at high risk of life-threatening arrhythmias. The significance of applying ECM for risk stratification is amplified by the lack of sensitivity of body surface measures (e.g., QT dispersion) at reflecting any underlying dispersion of repolarization.

Limitations

ECM provides EP information about the heart's epicardial surface; it does not directly reconstruct endocardial information in the 3-D myocardium. This is of lesser importance in relatively thin atrial tissue as opposed to ventricular. Septal arrhythmia sources, of great importance in scar-based ventricular arrhythmias, are thus less well characterized with ECM. Computation of endocardial activation is not yet possible because the electrical signal amplitude from the midwall and endocardium is much smaller. Nevertheless, in contrast to BSPMs, epicardial potentials provide high-resolution reflection of underlying intramural activity.

In addition, ECM can have limited success in defining components of arrhythmia pathways that involve small volumes of tissue, such as microreentry. Furthermore, the need to use CT limits the clinical application of ECM during intervention in the EP laboratory, where CT is not available. To render the ECM procedure more practical for mainstream adoption, newer methods for obtaining patient-specific geometry using biplane fluoroscopy or pseudo-3-D ultrasound have been developed and successfully tested in the context of ECM in the EP laboratory.

The need for CT scanning and associated radiation exposure should be weighed against value of ECM in the management of the individual patient and the potential reduction in subsequent procedural and fluoroscopic time, which warrant further studies. Nonetheless, ECM requires noncontrast CT at very low radiation (mean 148 mGy/cm). Also, cardiac geometry acquisition using an alternative technique (e.g., MRI) can help reduce radiation exposure.^{68,84}

INTRACARDIAC ECHOCARDIOGRAPHY

Catheter Design

Two types of ICE imaging systems are currently available: the mechanical ultrasound catheter radial imaging system and the electronic phased-array catheter sector imaging system.

Mechanical Ultrasound Catheter Radial Imaging System

In the mechanical ultrasound catheter (Ultra ICE) radial imaging system (EP Technologies, Boston Scientific, Sunnyvale, CA, United States), the ultrasound transducer is mounted at the end of a nonsteerable 9 Fr (110-cm length) catheter and has a single, rotating, crystal ultrasound transducer. An external motor drive unit rotates the crystal at 1800 rpm within the catheter to provide an imaging plane that is 360 degrees circumferential and perpendicular to the long axis of the catheter, with the catheter located centrally. Mechanical ICE uses imaging frequencies of 9 to 12 MHz, which provide near-field clarity (within 5 to 7 cm of the transducer) but poor tissue penetration and far-field resolution. As a result, these systems have not allowed clear imaging of the LA and PVs, except when they are introduced directly into the LA (transseptally). This technology lacks Doppler capability, and the catheter is not freely deflectable.

Electronic Phased-Array Catheter Sector Imaging System

In the electronic phased-array ultrasound catheter (AcuNav) sector imaging system (Acuson Corporation, Siemens Medical Solutions, Malvern, PA, United States), the ultrasound transducer is mounted on the distal end of an 8 or 10 Fr (90-cm length) catheter and has a forward-facing 64-element vector phased-array transducer scanning in the longitudinal plane. The catheter has a four-way steerable tip (160-degree anteroposterior and left-right deflections). The catheter images a sector (wedge-shaped) field in a plane in line with the catheter shaft and oriented in the plane of the catheter. Imaging capabilities include 90-degree sector 2-D, M-mode, and Doppler imaging (pulsed-wave, continuous-wave, color, and tissue Doppler), with tissue penetration up to 16 cm, and variable ultrasound frequency (5.5, 7.5, 8.5, and 10 MHz).

Imaging Technique

Using the Mechanical Radial Intracardiac Echocardiographic Catheter

Initially, all air must be eliminated from the distal tip of the ICE catheter by flushing vigorously with 5 to 10 mL of sterile water to optimize the ultrasound image. The ICE catheter is introduced through a long femoral venous sheath. Because the catheter is not deflectable, preshaped angled long sheaths are preferred to allow some steerability. The mechanical radial ICE catheter generates a panoramic 360-degree image perpendicular to the catheter, with the tip as a central reference point. The catheter is connected to the ultrasound console and advanced until the tip of the rotary ICE catheter image is in the RA.

When the transducer is advanced into the SVC, the ascending aorta, the right pulmonary artery, and occasionally the right superior PV are viewed. Withdrawing the catheter into the mid-RA brings the fossa ovalis and LA in view; the crista terminalis and aortic valve are usually visible in this view (Fig. 6.30). The LA, left PV orifices, and aortic root are imaged by positioning the transducer at the fossa ovalis. However, visualization of the LA and PV ostia is limited because of limited penetration depth. Withdrawing the catheter to the low RA allows visualization of the eustachian valve, lateral crista terminalis, and CS ostium (see Fig. 6.30). When the transducer is placed in the RV through the tricuspid valve and further advanced into the RVOT, both ventricles and the pulmonary artery can be visualized.

Fig. 6.30 Mechanical Radial Intracardiac Echocardiographic (ICE) Images From Different Levels in the Right Atrium (RA) and Superior Vena Cava (SVC). (A) With the transducer tip in the SVC, typical structures visible in this plane are the ascending aorta (AAO), right pulmonary artery (RPA), and right superior pulmonary vein (RSPV). (B) Withdrawing the ICE catheter into the mid-RA brings the fossa ovalis into view. Typical structures visible in this plane are the left atrium (LA), LA free wall (LAFW), aortic valve (AOV), and crista terminalis (CT). (C) Withdrawing the ICE catheter down to the RA floor visualizes the coronary sinus (CS) and inferior vena cava. (D) During transseptal puncture, tenting of the fossa is observed on the ICE. (Image provided courtesy of Boston Scientific. © 2018 Boston Scientific Corporation or its affiliates. All rights reserved.)

Using the AcuNav Catheter

A femoral venous approach is used for the insertion of the ICE catheter. The catheter is advanced to the RA under fluoroscopy guidance. ICE 90-degree sector scanning demonstrates a cross-sectional anatomical view oriented from the tip to the shaft of the imaging catheter's active face. The left-right (L-R) orientation marker indicates the catheter's

Fig. 6.31 Intracardiac Echocardiographic (ICE) Image of the Cavotricuspid Isthmus (CTI). The CTI (yellow arrows) is shown between the eustachian valve (EV, green arrow) and the tricuspid valve (TV, red arrows). RV, Right ventricle.

shaft side. When the L-R orientation marker is set to the operator's right, the craniocaudal axis projects left to right from the image and the posterior to anterior axis projects from the image top to bottom. Changing the L-R marker to the left side inverts the image but does not change the top-to-bottom image orientation. Image orientation can be adjusted to visualize targeted structures by simple catheter advancement or withdrawal, by tip deflection in four directions (anteroposterior and left-right), or by catheter rotation.

The AcuNav ICE catheter includes variable ultrasound frequency (5.5, 7.5, 8.5, and 10 MHz). Increasing ultrasound frequency improves axial image resolution; however, tissue penetration decreases and reduces imaging depth. An ultrasound frequency of 7.5 MHz is useful for imaging most cardiac structures. Frequency can then be increased (to 8.5 or 10 MHz) for imaging near-field structures, or decreased (to 5.5 MHz) for imaging far-field structures.

RA targets. All RA targets are visualized by advancing or withdrawing the ICE catheter to an appropriate level within the RA and rotating the catheter to bring the target into view. The best resolution of near-field and mid-field structures is obtained at an 8.5-MHz frequency. Once the catheter is advanced into the mid-RA with the catheter tension controls in neutral position (the ultrasound transducer oriented anteriorly and to the left), the RA, tricuspid valve, and RV are viewed. This is called the home view (see Fig. 4.11), and it can serve as a starting point; whenever the operator loses orientation, he or she can go back to the home view and start over. From the home view, counterclockwise rotation of the catheter brings the RA appendage into view, whereas anterior deflection of the catheter tip toward the RV allows visualization of the tricuspid valve and CTI (Fig. 6.31). The superior crista terminalis is visualized when the catheter is advanced to the RA-SVC junction in an anterior direction.

Interatrial septum. Gradual clockwise rotation of a straight catheter from the home view allows sequential visualization of the aortic root and the pulmonary artery, followed by the CS, mitral valve, the LA appendage orifice, and a cross-sectional view of the fossa ovalis (see Fig. 4.11). The mitral valve and interatrial septum are usually seen in the same plane as the LA appendage. Posterior deflection, right-left steering, or both, of the imaging tip in the RA, is occasionally required to optimize visualization of the fossa ovalis; the tension knob (lock function) can then be used to hold the catheter tip in position. Further

clockwise rotation beyond this location demonstrates images of the left PV ostia (see Fig. 4.11). The optimum ICE image to guide transeptal puncture demonstrates adequate space behind the interatrial septum on the LA side and clearly identifies adjacent structures (see Fig. 4.12).

LA structures. A 7.5- or 8.5-MHz imaging frequency optimizes visualization of LA structures and PVs beyond the interatrial septum. PV imaging is possible by first visualizing the membranous fossa from a mid-RA to low-RA catheter tip position. With clockwise catheter rotation, the LA appendage can be visualized, followed by long-axis views of the left superior and inferior PVs (Fig. 6.32; see Fig. 4.12). Further clockwise rotation of the catheter brings the orifices of the right superior and inferior PVs into view. The ostia of these veins are typically viewed en face, yielding an owl's eyes appearance at the vein's orifice. The LA appendage can also be visualized with the transducer positioned in the CS.

LV and RV targets. Imaging of each targeted LV structure at depths of 6 to 15 cm is accomplished with the catheter tip in a low-RA position. When the catheter transducer is placed near the fossa and oriented anteriorly and to the left, the left ventricular outflow tract (LVOT) and truncated LV are imaged. With clockwise rotation and slight adjustment of the transducer level, the mitral valve and LV apex can be viewed. To image the mitral valve in a long-axis, two-chamber view (LA, mitral valve, and LV), a mild degree of apically directed catheter tip deflection can be required. The RVOT, LVOT, and aortic root with coronary artery ostia can be imaged by advancing the catheter in the RA to the level of the outflow tracts (mid-RA), with an appropriate deflection to the right. The aortic valve can also be imaged in its cross section from this region (Fig. 6.33). A long-axis view of the LV can also be visualized by advancing the catheter with its anteriorly deflected tip into the RV and clockwise rotation against the interventricular septum (Fig. 6.34). Further clockwise rotation or right-left steering of the catheter tip allows a short-axis view of the LV, as well as the mitral valve (see Fig. 6.34). Pericardial effusions usually can be readily identified from these views. Withdrawing the catheter back to the base of the RVOT and rotating the shaft allow the RVOT to be visualized in its long axis, with a cross-sectional view of the pulmonic valve.

Clinical Implications

Transesophageal imaging has been used to guide ablation of VT and BTs, as well as transeptal catheterization, and for the closure of atrial septal defects or cardiac biopsy. This approach, however, has been limited in the interventional arena by aspiration risk and patient discomfort accompanying prolonged esophageal intubation, and it requires a second ultrasound operator to complete the study.

Previous human applications of ICE have been limited to those generated by the mechanical rotation of a single piezoelectric element in 6 to 10 Fr catheters. Miniaturization of these elements required the use of higher 10- to 20-MHz transducer frequencies, thus limiting ultrasound penetration to surrounding cardiac tissues. This technology has been applied to the imaging of RA structures in humans and animals, membranous fossa ovalis, crista terminalis, eustachian ridge, tricuspid annulus, and the SVC-RA junction in the region of the sinus node. However, visualization of the LA and PV ostia is limited using this system because of limited penetration depth, except when it is introduced directly into the LA (transseptally).

The electronic phased-array ultrasound system offers a deeper field of view, standard intracardiac visualization of specific right- and left-sided cardiac structures, as well as color flow and pulsed-wave and continuous-wave Doppler imaging by a single operator. These features have been of significant value for PV isolation procedures and LA linear ablation for AF.

Fig. 6.32 Intracardiac Echocardiographic (ICE) Images of the Left Pulmonary Veins With Transducer Placed in the Right Atrium (RA). (A) The RA, interatrial septum (green arrows), left inferior pulmonary vein (LIPV), left superior pulmonary vein (LSPV), and descending aorta are visualized. The Lasso catheter (yellow arrowheads) is visualized at the ostium of the LIPV. Color Doppler images of both LIPV and LSPV (B) and a pulsed-wave Doppler tracing (C) obtained from the LSPV are shown. LA, Left atrium.

Several practical uses for ICE have emerged in the setting of EP procedures, including the following: (1) assessment of catheter contact with cardiac tissues; (2) determination of catheter location relative to cardiac structures (specifically useful in otherwise difficult to localize areas; e.g., the PVs, papillary muscle); (3) guidance of atrial septal puncture, particularly in the setting of complex or unusual anatomy; (4) facilitation of deployment of mapping or ablation systems (e.g., PV encircling devices, noncontact mapping systems, and basket technologies); (5) visualization of evolving lesions during RF energy delivery (both changing tissue echogenicity and microbubbles reflect tissue heating, with the latter providing a signal for energy termination); (6) defining LV scar to guide substrate-based ablation of scar-related VT (Fig. 6.35); (7) evaluation of cardiac structures before and after intervention (e.g., cardiac valves and PVs); (8) assessment of PV anatomy,

dimensions, and function via 2-D anatomical imaging and Doppler physiological measurements; (9) assessment of complications (e.g., tamponade, electromechanical dissociation, or thrombus formation; see Fig. 32.1); (10) identification of the anatomical origin of certain arrhythmias (e.g., ICE can facilitate ablation of inappropriate sinus tachycardia or sinus nodal reentrant tachycardia); (11) definition of the proximity of the catheter tip and coronary arteries (during mapping and ablation of arrhythmias originating from the aortic cusp); and (12) identification of esophageal location.⁸⁵

As mentioned previously, the CARTO-Sound Image Integration Module incorporates the electroanatomic map to an ICE volume map of the cardiac chamber derived from a phased-array transducer catheter incorporating a position sensor (Sound-Star, Biosense Webster), which may be used as a stand-alone tool to guide navigation and ablation or

Fig. 6.35 The CARTO-Sound Image Integration Module to Guide Scar-Related Ventricular Tachycardia Ablation. (A) Intracardiac echocardiographic (ICE) image showing a long-axis view of the left ventricle (LV) using a 10 Fr phased-array transducer catheter. The endocardial surface of the LV is traced. Note aneurysmal wall thinning of the anteroapical of the LV (traced in green) as compared with normal wall thickness in the LV base (traced in red). (B) Integration of the CARTO-Sound volume and the electroanatomic voltage map of the LV (modified anterior view).

as a facilitator of CT/MRI image integration (see Fig. 6.4). This navigation approach has been successfully utilized for catheter ablation of AF. In addition, 3-D ultrasound images can potentially yield anatomically accurate chamber geometries and identify scar in the LV (both by wall thickness and motion) to facilitate substrate mapping and ablation of post-infarct VT (see Fig. 6.35).

COMPUTED TOMOGRAPHY AND MAGNETIC RESONANCE IMAGING

Fundamental Concepts

During catheter ablation procedures, the catheters are usually manipulated under the guidance of fluoroscopy. However, fluoroscopy does not provide adequate depiction of cardiac anatomy because of its poor soft tissue contrast and the 2-D projective nature of the formed image, which hinders its application for complex procedures such as AF ablation. On the other hand, CT and MRI images offer anatomical detail in 3-D. However, these images are presented out of the context of the ablation catheter, thus greatly diminishing their potential value. An optimal strategy would therefore be to integrate the 3-D images generated by CT or MRI with the electrical and navigational information obtained by an interventional system. This can be achieved through the process of integration. Image integration refers to the process of aligning the preprocedural cardiac CT and MRI images with the real-time 3-D electroanatomic maps reconstructed from multiple endocardial locations. The process of image integration consists of three steps: preprocedural CT and MRI image acquisition, image segmentation and extraction, and image registration.

Image Acquisition

Cross-sectional or axial CT or MRI scans are acquired at sufficient resolution to delineate cardiac structures less than 1 to 2 mm in thickness. Images at 0.625-mm thickness can be reconstructed from images obtained at 1.25-mm intervals with currently available multirow helical scanners. A simultaneous ECG is recorded to assign the source images retrospectively to the respective phases of the cardiac cycle. MRI images are similarly obtainable, although at a slightly lower spatial resolution. Reconstructing any cardiac chamber in 3-D from the axial images is performed using any one of various software packages.

Image Segmentation

Image segmentation refers to the process of extracting the 3-D anatomy of individual cardiac structures from its surrounding structures. Methods

of image segmentation include thresholding, boundary detection, and region identification. Thresholding involves assigning pixels with intensities lower than a threshold to one class and the remaining pixels to a different class. Connecting adjacent pixels of the same class then forms regions. Boundary differentiation methods use information about intensity differences between adjacent regions to separate the regions from each other. Region identification techniques then form regions by combining pixels of similar properties. For cardiac ablation procedures, the volume of cardiac structures is extracted from the whole-volume data set using a computerized algorithm that differentiates the boundary between the blood pool (which is high in contrast) and the endocardium (which is not contrast enhanced). This allows for clear differentiation between the chamber lumen and endocardial wall (eFig. 6.7). Subsequently, the volumes of individual cardiac structures are separated from each other with the use of another algorithm capable of detecting their boundaries. Using a third algorithm, the segmented volumes for individual cardiac structures are extracted as 3-D surface reconstructions. The segmented volumes can be viewed from an external perspective or from within the chamber using virtual endoscopic or cardioscopic displays. These images, in addition to providing a road map for ablation, can also be used for registration.

Image Registration

Although the segmented structures are highly useful for visualizing the cardiac structures and characteristics of the tissue forming that structure, they do not convey the physiology of an arrhythmia. Integrating that physiology, as captured by electroanatomic or noncontact mapping with the spatial information contained in the CT or MRI images, requires the registration of activation or voltage data to an appropriate location on a 3-D representation of a chamber. This is of critical importance in that it establishes the relationship between anatomy and physiology as required for the structure- and activity-based understanding of arrhythmias and for enabling image-guided intervention. Image registration refers to superimposing the 3-D CT/MRI surface reconstruction onto the real-time electroanatomic maps yielded by the 3-D mapping system (see Fig. 6.3).⁸⁶

During registration, the assumption is made that the anatomy of the organ being registered has not changed. Two computerized algorithms are used to accomplish the image registration process: landmark registration and surface registration. Landmark registration aligns the 3-D CT/MRI image reconstruction with corresponding electroanatomic maps through linking two sets of corresponding fiducial points in each set of the images to be registered. Under the guidance of fluoroscopy

eFig. 6.7 CT Image Segmentation and Integration With Electroanatomic Mapping (CARTO) Data. (A) Three-dimensional reconstruction of the heart and part of the spine from the two-dimensional CT image (posteroanterior view). (B and C) Individual cardiac chambers are segmented from each other using computerized algorithms capable of detecting their boundaries (aorta, *red*; left atrium [LA], *yellow*; left ventricle, *green*; pulmonary artery, *blue*; right atrium, *orange*). (D) and (E) The cardiac chamber is selected (LA in this case), and others are deleted. (F) Integration of CT and electroanatomic mapping (CARTO) data. Shown is a left lateral cardioscopic view of the ostia of the left pulmonary veins (PVs) during PV electrical isolation. Radiofrequency applications (*small red circles*) were deployed at the posterior aspect of the ostium of the left superior PV (LSPV). The ablation (*Abl*) catheter tip is positioned at the inferior aspect of the LSPV.

or ICE, or both, at least three landmark pairs are created by real-time catheter tip locations on the interventional system being used for registration and then placed on their estimated locations on the 3-D CT/MRI image reconstructions. Using more landmark points increases the accuracy of the registration process. Surface registration is an algorithm that attaches the acquired endocardial points to the closest CT/MRI surface to compose the best fit of the two sets of images by minimizing the average distance between the landmarks, and the distance from multiple endocardial locations, to the surface of 3-D CT/MRI image reconstructions. Surface registration complements landmark registration to improve the registration accuracy. However, because of surface indentation and potentially missed areas during mapping, the acquired electroanatomic map does not represent the perfect anatomy of the cardiac chamber.⁸⁶

Computed Tomography Overlay

A novel application (EP Navigator prototype, Philips Healthcare, Best, The Netherlands) has been developed to superimpose a preacquired segmented 3-D CT image of the LA over real-time fluoroscopy system (“CT overlay”) to help in guiding ablation of atrial arrhythmias, particularly AF. This application can be used on monoplane or biplane fluoroscopy. It permits fluoroscopy-directed guiding of an ablation catheter and diagnostic catheters in a virtual 3-D model of the LA, and subsequent tagging of ablation sites on the registered 3-D image without the simultaneous use of an electroanatomic mapping system, thus facilitating the creation of continuous lines and returning to critical ablation sites. Furthermore, it is feasible to identify and segment the esophagus on the CT scan, which can subsequently be overlaid on the fluoroscopic images along with the cardiac structures.

Image Integration Technique

Image Registration Using CARTO-Merge

The preacquired CT/MRI digital imaging data are imported by a CD into the CARTO system equipped with commercially available software (CARTO-Merge image integration software module) that allows structures of interest to be easily and quickly segmented and reconstructed in 3-D. The segmented images are then imported into the real-time mapping system. Once created using the CARTO system (as described previously), the electroanatomic map of the cardiac chamber is “fused” to the CT/MRI. The most frequently used registration technique is a combination of landmark registration and surface registration. Landmark registration involves the 3-D orientation of the imported CT/MRI image on the *x*, *y*, and *z* axes, and requires the acquisition of at least three noncollinear endocardial landmark points using the mapping-ablation catheter. The precise location of these on the 3-D image is a critical factor in this technique and remains challenging. Biplane fluoroscopy, angiography, and ICE can be used to facilitate identification of the landmark point. Catheter contact is ensured by fluoroscopy visualization of the catheter mobility in relation to the cardiac motion and by a discrete electrogram. The estimated corresponding locations of these endocardial landmark points are then marked on the imported 3-D CT/MRI image, thus creating a landmark pair, with one landmark point on the real-time electroanatomic map and the other on the 3-D CT/MRI image.

Landmark registration approximates the electroanatomic map to the 3-D CT/MRI surface reconstruction by matching the landmark pair. Surface registration fits the 3-D CT/MRI surface reconstruction with the electroanatomic map points by rendering the smallest average distance of the two datasets. Although the registration of surface points should improve alignment of the two images, registering points from the entire surface of the cardiac chamber involves the risk of incorporating errors related to potential indentation of the chamber wall and

distortion of chamber geometry resulting from the pressure of the mapping catheter on the most mobile regions. The mapping system then provides an average tip-to-surface distance, which ideally should be less than 2 mm. While manipulating the catheter during ablation, the projected catheter distance to the surface is used as an additional guide to assess catheter contact. This can be complemented by information from electrograms recorded by the catheter, fluoroscopy, and ICE.

Image Registration Using CARTO-Sound

Real-time ICE images can provide accurate chamber geometries. The CARTO-Sound utilizes an 8 or 10 Fr phased-array ICE catheter with an embedded navigation sensor (SoundStar, Biosense Webster), which records individual 90-degree sector image planes of the cardiac chamber of interest, including their location and orientation, to the CARTO workspace. To correct for respiratory phase, all ICE images should be acquired during expiratory breath-hold. Once the CARTO-Sound volume map of the cardiac chamber is created, registration is performed using CARTO-Merge software. First, the CT/MRI image is visually aligned with the ICE-created cardiac chamber anatomical shell. Second, landmark registration is performed whereby three echocardiographically discrete anatomical sites identified with ICE (landmark points) are tagged on the ICE contour and matched to a corresponding location on the CT/MRI image. Finally, the CARTO-Merge surface registration algorithm is performed. This algorithm attempts optimally to juxtapose, or integrate, the CT/MRI image spatially with the CARTO-Sound model to minimize the average distance between each point on the ICE-created anatomical rendering of the cardiac chamber and the corresponding CT/MRI image, thus permitting the CT model to guide navigation.⁸⁵

Registration is based on the best fit between the cardiac chamber surface reconstruction obtained with each ICE contour and the corresponding CT/MRI image, and it is not based on the LA volume obtained with ICE and the corresponding CT/MRI image. ICE-guided focused endocardial surface registration seems to be superior to landmark registration in achieving a better alignment between the CT/MRI image and the electroanatomic map. The 3-D ultrasound images can help create anatomically accurate, real-time chamber geometries, and eliminate chamber deformity (as often happens with contact mapping), potentially to yield more accurate CT/MRI registration.

Image Registration Using NavX Fusion

The cardiac chamber of interest is segmented and reconstructed in 3-D from CT/MRI slices using EnSite Verismo software. The 3-D virtual anatomical geometry of the cardiac chamber is created using NavX Fusion (as described previously). The CT/MRI reconstruction of the mapped cardiac chamber is displayed on a split screen and used to guide finer anatomical definition with the ablation catheter and help edit the virtual 3-D geometry to eliminate “false space.” Subsequently, “field scaling” is applied to the geometry to compensate for variations in impedance between the heart chambers and venous structures, and render the geometry and navigational space more physiologically relevant and to more closely resemble the CT/MRI image. The field scaled geometry is fused to the CT/MRI in two stages, termed *primary (rigid) fusion* and *secondary (dynamic) fusion*. Primary fusion uses three fiducial (i.e., landmark) corresponding points on the created geometry and the CT/MRI image to superimpose, or lock together, both images (Fig. 6.36). These points are chosen to ensure reasonable 3-D anatomical separation and allow orientation of the CT/MRI, but the registration error is high. Therefore secondary fusion points or fiducials are applied to the primary fused geometry at sites of local mismatch between the two superimposed geometries.

In this unique component of image fusion, the created geometry surface is molded to the CT/MRI surface while also “bending” the 3-D

Fig. 6.36 Integration of CT and EnSite NavX Electroanatomic Mapping Data. Shown are posteroanterior (*left*) and left lateral views (*right*) of the electroanatomic contour acquired with catheter manipulation in the left atrium (LA) during atrial fibrillation ablation overlaid on a CT image of the left atrium acquired several days earlier. Small white circles are tagged sites at which radiofrequency energy was applied. Circumferential LA ablation, as well as linear ablation across the LA roof and later mitral annulus, were performed. LAA, Left atrial appendage; LIPV, left inferior pulmonary veins; LSPV, left superior pulmonary veins; RIPV, right inferior pulmonary veins; RSPV, right superior pulmonary veins.

navigation space within the geometry. This process is continued, adding supplemental (usually more than 15) fiducial point pairs until good correspondence between the NavX geometry and CT/MRI models is achieved. For example, if the anterior wall of the geometry is fused anteriorly to the CT/MRI, the catheter location also will be moved so that when the catheter is repositioned on the anterior wall after fusion, it should be visualized on the CT/MRI surface and not within the bounds of the original perfusion geometry.

Although the principle of CT/MRI image integration is common to both the EnSite NavX Fusion and CARTO-Merge systems, there is a significant difference in how registration is achieved. As described previously, the EnSite system uses a dynamic registration process (with four or more fiducial points) to optimize both rotation and stretching of the surface of the NavX geometry to match the CT/MRI. With the CARTO-Merge system, the whole registration process is rigid with rotation of the CT/MRI to minimize the distance between the surface of the anatomical model generated and that of the CT, but no stretching of the model itself. Despite this difference, the registration error is similar with both techniques (CARTO-Merge, 2.3 ± 1.8 mm, vs. EnSite NavX Fusion, 3.2 ± 0.9 mm).

Image Registration Using Fluoroscopy (Computed Tomography Overlay)

The preacquired CT data set is imported into the software, the cardiac chamber of interest is automatically segmented, and a 3-D volume of the LA and PVs is constructed. Before CT registration is performed, the patient must be properly positioned, and the structure of interest must be isocentered in two orthogonal fluoroscopic projections. Initial registration is based on the heart contour to allow for quick alignment of the CT-rendered volume with the fluoroscopic image. On an antero-posterior fluoroscopic projection (without contrast injection), the CT volume overlay is aligned by first using the right lateral atrial contour. The rest of the cardiac contour then is superimposed on the fluoroscopic image, based on the best visual estimate. Subsequently, fluoroscopic identification of intracardiac landmarks by catheter manipulation within the LA and PVs improves the overlay accuracy (e.g., caudal drop of the catheter when withdrawing from a PV into the LA helps identify the

PV ostium; insertion of the ablation catheter into readily identifiable anatomical landmarks such as PV branches immediately connected to PV ostium, accessory PVs; and looping of the ablation catheter in the LA resulting in circumferential catheter-endocardium contact). Finally, angiography of the right and left superior PVs (sequentially or simultaneously) in two orthogonal views is performed to adjust the CT image further and improve registration by matching the superior border of the LA and the superior PV ostia, as well as certain landmarks, such as PV bifurcations, between 3-D image and fluoroscopy.

After registration and locking, the 3-D CT image is always depicted at the same angle as the fluoroscopy (i.e., the CT-generated volume rotates on the screen following the rotation of the C-arm), thus allowing for constant visualization of the CT and fluoroscopic images under the same viewing angle. The transparency of the overlaid CT 3-D volume is adjustable, to allow visualization of the catheters in the fluoroscopic image. In addition, the 3-D image can be clipped with a customizable cutting plane, to permit internal (endoscopic) views. Moreover, tags can be placed on the surface of the registered 3-D image to mark ablation sites and other sites of interest.

Clinical Implications

The 21st century has also seen the rapid development of integrated, anatomically based atrial and ventricular mapping and ablation. This progress has been driven by a realization of both the critical coupling and dependence of arrhythmias on their underlying anatomy and the limitations of surrogate geometries of contemporary mapping systems for reflecting that anatomy. Over this same time frame, rapid CT and MRI imaging systems have emerged as the mainstays of imaging in the EP laboratory and have been used to plan or guide ablation. Helical 16- to 64-row CT and MRI studies provide a broad anatomy library of an individual patient at one point in time. Segmented CT volumes can be downloaded on the CARTO and NavX platforms. These systems are able to register the surrogate map fully onto actual CT and MRI anatomy; they also enable the integration of electroanatomic mapping with preacquired CT and MRI images, and allow real-time visualization of the location and orientation of the catheter tip within the registered CT anatomical framework (see Fig. 6.3; eFig. 6.7).

The use of registered CT and MRI images to guide catheter ablation presents a significant advantage over the less detailed surrogate geometry created by previously available 3-D mapping systems. Because it provides detailed anatomical information on the catheter tip location in relation to the true cardiac anatomy, the image integration technique has the potential to facilitate many ablation procedures, especially anatomically based ablation strategies, such as AF ablation and ablation of intraatrial reentrant tachycardias following corrective surgery for congenital heart diseases. Initial experience has shown that the registered CT and MRI of LA reconstructions can provide accurate information on the catheter tip location in relation to the important LA structures, such as the PV ostium and LA appendage. The real-time update of the catheter tip location and the marking of ablation lesions on the detailed 3-D image can potentially improve the quality of lesion sets, reduce complications, and shorten procedure and fluoroscopy times.

In addition, CT and MRI integration has been increasingly used to guide substrate-based ablation procedures for scar-related VT (see Fig. 6.37, eFig. 6.8, and Fig. 6.38). Ventricular scar and its border zone represent the target of “substrate modification” VT ablations; therefore, an exact anatomical delineation is critical. Multiple imaging modalities detailing the LV or RV substrate in a 3-D format can be visualized and displayed simultaneously with the electroanatomic 3-D ventricular voltage

map. These imaging approaches can be used to correctly predict abnormal voltage locations in advance of the mapping procedure, which may allow the electrophysiologist to concentrate on areas of likely myocardial scar, obviate the need to perform a complete point-by-point voltage mapping, identify falsely low-voltage recordings in areas of normal perfusion due to suboptimal catheter contact, as well as reduce procedure time and fluoroscopic exposure. In addition, some imaging modalities are able to characterize the transmural extent and intramyocardial location of scar tissue, which can potentially help identify intramural and epicardial arrhythmia substrate, overcoming a limitation of endocardial voltage mapping.^{86,87} In addition, real-time integration of CT images of the phrenic nerve and coronary arteries can help guide epicardial ablation and minimize the risk of injury to these structures.^{88,89}

Registration of a preacquired 3-D CT image on fluoroscopy potentially combines the accuracy of CT with the real-time fluoroscopy to guide catheter ablation of AF. Compared with an established and widely used electroanatomic mapping technique for PV antrum isolation, procedural duration can be shortened significantly without a concomitant increase in radiation burden. An additional advantage to CT overlay is the ability to perform a quick repeat registration in case of major changes in a patient's position. However, unlike the CARTO system, which provides notification for significant patient movements, the

Fig. 6.37 Image Integration to Guide Catheter Ablation in Scar-Related Ventricular Tachycardia (VT). (A) Imaging is used to segment the cardiac chambers, epicardium, coronary sinus, as well as coronary arteries and left phrenic nerve to facilitate ablation of scar-related VT. In patients with ischemic or nonischemic cardiomyopathy, the structural substrate is segmented on imaging as areas of late gadolinium enhancement on cardiac magnetic resonance images (MRI) (B), and/or areas of wall thinning (less than 5 mm, note double arrows) on multidetector CT scans (C). In patients with arrhythmogenic right ventricular cardiomyopathy, the structural substrate is segmented as areas of myocardial hypo-attenuation on multidetector CT (D). All segmentations are used to compute a 3-D cardiac model (E; cardiac MRI and CT fusion: left ventricular endocardium is shown in gray, epicardium in translucent white, dense scar from cardiac MRI in orange, gray zone in yellow, coronary arteries in red, coronary sinus in blue, left phrenic nerve course in green). (From Yamashita S, Sacher F, Mahida S, et al. Image integration to guide catheter ablation in scar-related ventricular tachycardia. *J Cardiovasc Electrophysiol*. 2016;27:699–708.)

eFig. 6.8 Image Integration in Ventricular Tachycardia (VT) Ablation. Examples of image-guided VT ablation in patients with ischemic cardiomyopathy (ICM, left panels), nonischemic cardiomyopathy (NICM, middle panels), and arrhythmogenic right ventricular cardiomyopathy (ARVC, right panels). Bipolar voltage maps are shown on the top row, detector computed tomography-derived substrate in orange on the second row, and cardiac magnetic resonance-derived substrate in green on the third row. Blue dots indicate local abnormal ventricular activity (LAVA). Blue line in the second column indicates the course of the left phrenic nerve. *Endo*, Endocardial; *Epi*, epicardial. (From Yamashita S, Sacher F, Mahida S, et al. Image integration to guide catheter ablation in scar-related ventricular tachycardia. *J Cardiovasc Electrophysiol*. 2016;27:699–708.)

Fig. 6.38 Computed Tomography Integration on NavX Electroanatomic Mapping System. (A) After field scaling and registration with four points (left ventricular apex, mitral annulus, aortic root, and coronary sinus), additional fusion points on the local mismatch sites (yellow points) were applied. (B) Real-time integrated image can be monitored with a catheter position in the coronary sinus during procedure (white arrows). 3-D, Three-dimensional; MDCT, multidetector computed tomography. (From Yamashita S, Sacher F, Mahida S, et al. Role of high-resolution image integration to visualize left phrenic nerve and coronary arteries during epicardial ventricular tachycardia ablation. *Circ Arrhythm Electrophysiol.* 2015;8:371–380.)

operator needs to be alert on discrepancies between catheters and anatomy, and must check registration in case of suspected movement. In addition, with the CARTO system, one can return to the catheter-based LA reconstruction without Merge, which may be more accurate than the CT image.

Limitations

Although CT and MRI provide exquisite images of the underlying structures relevant in arrhythmogenesis, they are limited by the requirement of off-line generation of the CT and MRI libraries and the inability to reflect all phases of the cardiac cycle during an arrhythmia. Because CT and MRI are performed prior to the ablation procedure, registration error can arise from interval changes in the heart size because of differences in rhythm, rate, contractility, or fluid status. Performing image registration and ablation procedures within 24 hours after CT and MRI scans and CT and MRI image acquisition and image registration during the same rhythm may help limit interval changes. This situation is confounded by the inevitable imperfection of the created virtual geometry of the cardiac chamber. These factors can impede the clinical utility of image integration in approximately 25% of patients.

Furthermore, the static images of the registered CT and MRI reconstructions provide little information on true catheter-tissue contact. In addition, because the initial landmark points are picked up by the operator using fluoroscopy, the exact location of these points in the 3-D space can be deceptive, and registration errors in the identification of these points are very common, even when angiography and ICE are used for guidance. In addition, because multiple points are needed for surface registration, the accuracy of chamber reconstruction is directly dependent on the number of points taken and the position of the catheter, thus adding a significant amount of time and a manual component to the process.

To overcome some of these limitations, fusion of real-time ICE images with those generated by CT and MRI scans is becoming

available and can provide a more real-time interactive display, as well as real-time information on catheter-tissue contact and RF lesion formation. In addition, it is highly likely that subsequent generations of CT or MRI scanners will be sufficiently fast to permit real-time or almost real-time imaging for interventional guidance. Studies have demonstrated the ability to merge the 3-D CT and MRI images with real-time 2-D fluoroscopy images for navigation on virtual anatomy, because the images can be corrected against the background of real-time fluoroscopy as needed.

The accuracy of registration remains the subject of investigation. 3-D image integration aims at improving the operator's perception of the catheter spatial location in relation to the patient's cardiac structures. However, the success of this approach is primarily dependent on the accuracy of the image integration process. Even if the 3-D cardiac chamber image provides an accurate model of a matched phase of the chamber volume at the time of the procedure, it needs to be accurately registered to the procedural chamber orientation to provide reliable navigation. Current registration algorithms depend on accurate catheter geometry; this requires an accurate update of 3-D coordinates of the catheter tip, as recorded and displayed on the computer image. The exact location of the initial fiducial points picked by the operator using fluoroscopy in the 3-D space can be deceptive. Movement of the catheter tip is complex and is affected by wall motion and respiration. Point collection should therefore be gated to the same phase of the cardiac and respiratory cycle as the CT or MRI scan. In addition, catheter tip pressure can cause tenting of the chamber wall, thereby distorting the chamber geometry. Stability of catheter contact with the endocardial wall should also be optimized. Catheter contact can vary with the type of ablation catheter and introducer sheath, as well as the degree of regional wall motion; for example, the mitral annulus and appendage are more dynamic than the posterior atrial wall. Ideally, geometry points should be collected from stable catheter positions. The operator can then accept good points or delete bad points. This process can be aided by

fluoroscopy, electrogram morphology, and confirmation of the catheter tip location on ICE. However, the process still remains a subjective art.

Several studies of AF catheter ablation have reported success using different integration modalities with CT or MRI, by using either non-contact mapping or fluoroscopy as a second integrated image. The registration technique has also varied, including three- or four-point registration or surface registration. Alternatively, a single point and the surface have been used as well (visual alignment). Different techniques for point localization have been reported, including fluoroscopy alone, angiography, or ICE for direct visualization of the catheter at the designated site. The mean error for surface registration in most studies varied between 1.8 and 2.7 mm; one study that compared the landmark registration with and without surface registration found that surface registration increases the accuracy of image integration. On the other hand, a more recent study found that the most accurate landmark registration is achieved when posterior points are acquired at the PV-LA junction, whereas points acquired on the anterior wall, LA appendage, or other structures outside the LA, such as the CS or SVC, afford less accuracy. In addition, surface registration usually results in shifting the landmark points away from the initially acquired position on the corresponding PVs using ICE. Furthermore, accurate surface registration does not guarantee accurate alignment with the important anatomical structures. Another report found that serious inaccuracies of the CARTO-Merge image integration algorithms still exist, despite using the precautions discussed earlier.

It is important to recognize that the registered CT model still is prone to subjective inaccuracies and should remain only a guide, and a combination of fluoroscopy and the electrogram appearance is frequently used in assessing contact with the endocardial surface and the true position of the catheter. Further, registration quality has not yet been shown necessarily to correlate with ablation accuracy.

THREE-DIMENSIONAL ROTATIONAL ANGIOGRAPHY

Fundamental Concepts

Three-dimensional rotational angiography combines the accuracy of direct angiography with the benefits of computer animation and supplements conventional 2-D fluoroscopy to provide real-time representation of cardiac structures. Its feasibility and clinical utility in the setting of LA imaging and AF ablation have been described. This method provides rapid intraprocedural visualization of LA anatomy and of important nearby structures such as the esophagus. Prior studies have demonstrated that the diagnostic value of 3-D rotational angiography is comparable to that of CT imaging.⁹⁰

The principle of 3-D rotational angiography is similar to the CT scan, in which images acquired from different angles are reconstructed to a 3-D image. The C-arm x-ray system is rotated around the patient over 240 degrees to create a circumferential run of many exposure images of the region of interest distributed over the 360-degree (or similar) trajectory. To improve differentiation of the cardiac structures, the cardiac chamber of interest can be opacified with a contrast medium injected either directly into the LA or indirectly into the right side of the heart, in which case rotation of the fluoroscopic system is started after passage of the contrast medium through the lungs. The esophagus can be opacified using a barium paste prior to the image acquisition. The rotational angiographic images of the LA, PVs, esophagus, and other surrounding structures can be segmented and registered with the fluoroscopy on a specialized computer system (EP Navigator; or DynaCT Cardiac, Siemens, Forchheim, Germany). The latest version of the software allows registration of the segmented 3-D volume on a live fluoroscopy screen.^{90,91}

Imaging Technique

First, the patient must be properly positioned, and the structure of interest must be isocentered. The patient's arms may be extended above the head to reduce mass artifact. Oral contrast (5 mL barium sulfate esophageal cream) is administered immediately prior to initiation of the rotational run, and once it is visualized in the esophagus, IV contrast may be injected into the main pulmonary artery, RV, RA, or IVC via a 6 Fr pigtail catheter to obtain adequate levophase opacification of the LA. In general, contrast injection at the IVC-RA junction results in adequate LA and PV opacification in most patients. In addition, this method is technically simpler and potentially safer than more downstream injections. Higher amounts of contrast and longer injection time are generally used with RA and IVC injections than with main pulmonary artery injection. Direct contrast injection into the LA was described and seemed to provide great detail of LA and PV anatomy, but it required a high-dose (30 to 50 mg) adenosine injection immediately prior to the rotational run. Transient cessation of contractions prevents anterograde washout of contrast from the PVs, thus keeping them opacified during the rotational run. Deep sedation, intubation, and RV pacing are usually needed to counteract apnea and asystole produced by adenosine. In addition, high doses of adenosine are not tolerated by the conscious patient because of the induced flush and dyspnea. Given such complexities, this method can be more difficult to implement in clinical practice.⁹⁰

For injection at the RA-IVC junction, 80 to 100 mL of contrast is injected over 4 seconds via a pigtail catheter using a power injector. The C-arm is rotated over a 240-degree arc (120-degree RAO to 120-degree LAO view) in a 4.1-second period. The x-ray acquisition speed is 30 frames per second, which results in a total of 120 frames in the rotational run. Continuous fluoroscopic monitoring for contrast appearance in the LA is used to trigger the rotational run, based on visual guidance rather than on an empirically determined delay. The patient is instructed to stop breathing immediately prior to initiation of the rotational run to prevent respiratory movement of the structure of interest and inadequate reconstruction. Normal breathing can be resumed immediately on the completion of rotation.

The rotational angiogram is judged to be adequate when the LA is filled with contrast during most of the run and antral portions of all PVs are opacified without truncation. A resultant movie file is then transferred to an EP Navigator workstation to be segmented and overlaid on a live fluoroscopy screen. After the catheters are advanced into the LA, the 3-D image is used for navigation. With registration of the 3-D volume, all movements of the C-arm are translated into the appropriate rotation or shift, thus keeping the relationship between the fluoroscopic heart shadow and reconstructed image unchanged.

Image integration of intraprocedural rotational angiography-based 3-D reconstructions of LA and PVs into the electroanatomic mapping system (EnSite Velocity or CARTO-Merge) has become feasible. The images of the segmented LA are saved on a compact disc and transferred to the electroanatomic mapping system by using custom-designed software and integrated without further segmentation (eFig. 6.9).

Theoretically, no registration for 3-D rotational angiography image overlay is necessary if the original x-ray table position and the patient's position during the rotational run are maintained. However, moving the x-ray table is often required after 3-D rotational angiography, especially given the fact that intracardiac catheters should be placed only after the rotational run to prevent artifacts. Therefore registration is often necessary because in its current iteration, overlay movement is linked only to C-arm rotation and not to x-ray table repositioning. Several registration methods using different primary landmarks, such as catheter placement, heart contour, and PV angiography, have been

eFig. 6.9 Integration of Rotational Angiography With Electroanatomic Mapping and CT. (A and B) Rotational angiography three-dimensional (3-D) reconstruction (*left*) and NavX electroanatomic map (*middle*) of the LA shown in the anterior-posterior (A) and posterior-anterior (B) views before and after (*right*) merging. Also shown are a multipolar coronary sinus catheter (*both panels*, left side) and ablation lesion set. Pulmonary veins are shown in gray in both panels. The left atrium (LA) body is shown in gray for rotational angiography 3-D reconstruction and in blue for NavX in both images. Left atrial appendage surface is shown in red. (C and D), CT image (*left*) and NavX map (*middle*) of the LA shown in the anterior-posterior (C) and posterior-anterior (D) views before and after (*right*) merging. The ablation lesions are also shown in both panels. The fused LA shell is constructed from the CT surface data (*red*) and NavX surface data (*blue*). The left atrial appendage is shown in red in both panels. Note a more realistic appearance of the merged map with both imaging modalities. (From Anand R, Gorev MV, Poghosyan H, et al. Prospective randomized comparison of rotational angiography with three-dimensional reconstruction and computed tomography merged with electro-anatomical mapping: a two center atrial fibrillation ablation study. *J Interv Card Electrophysiol*. 2016;46:1–9.)

evaluated. These methods are particularly useful when registering previously obtained CT images on live fluoroscopy (i.e., CT overlay), which is another imaging input available in the EP Navigator (as discussed previously).^{90,91}

The current software version allows for the inner surface of the LA and PVs to be visualized (endoscopic view), further aiding the physician when navigating around the LA. Ablation points can be marked on the overlaid 3-D rotational angiography model to track the completeness of lesions. LA proximity to the esophagus can be evaluated and catheter ablation modified as necessary to avoid ablation near the esophagus.

Clinical Implications

One of the advantages of 3-D rotational angiography over conventional 2-D fluoroscopy is the capability of depth perception and volume appreciation. 3-D rotational angiography provides direct visualization of cardiac structures, whereas electroanatomic methods require either operator imagination or confirmation via other imaging modalities, such as CT. Although preprocedure CT/MRI images provide visualization of the LA and the PVs, and facilitate integration with the electroanatomic mapping systems, a significant drawback is the time lag to the actual procedure. Interval changes in volume status, respiratory phase, and cardiac rhythm can result in temporal changes in the size and location of the anatomical structures between the time of image acquisition and the registration process. These limitations can be overcome by intraprocedural acquisition of the LA volume and PV anatomy; 3-D rotational angiography can be performed immediately before ablation using the same fluoroscopic imaging system, thus providing realistic anatomical detail at the time of the intervention.⁹⁰

Other advantages of 3-D rotational angiography technology include quick and accurate repeat registration of the 3-D volume in case of patient movement not requiring a new map, as is frequently the case with electroanatomic methods.

Despite exclusively fluoroscopic guidance of the ablation catheter using the 3-D rotational angiography technology, total fluoroscopy time and fluoroscopy time for PV isolation have been comparable to reported times for AF ablation procedures performed with different nonfluoroscopic mapping systems. In addition, 3-D rotational angiography has the potential to eliminate the need for preprocedural CT/MRI imaging, and the radiation exposure is less than that of CT scanning (estimated at 2.2 ± 0.2 mSv exposure with one rotational angiography run).

Imaging by 3-D rotational angiography should not be confined to the LA and PVs. Other cardiac structures (current possibilities include RA and RVOT) can be easily visualized by timing the rotational run with the passage of contrast through the structures. The possibility of “whole heart” imaging has been reported.

Limitations

The use of contrast makes 3-D rotational angiography a less appealing option for patients with heart failure or renal insufficiency. In addition, the technique is sensitive to patient movements during the study period.

One shortfall of 3-D rotational angiography is the absence of streaming electrogram data. In addition, because of the lack of respiratory compensation in the 3-D rotational angiography-fluoroscopy fusion, the end-expiratory phase is used as a reference for monitoring the position of the ablation catheter tip during RF application.

Proper isocentering is important to obtain adequate 3-D rotational angiography. Concerns have been raised about the frequent difficulty in fitting the LA and PVs into one rotational run with the commonly used detector. However, with proper isocentering, even a dilated LA and the PV anatomy can be adequately imaged; truncation can occur more easily if the structures of interest are not at the center of rotation.

3-D rotational angiography is evolving into a true online imaging tool; however, further refinements are needed before it can be widely adopted. These include incorporation of respiratory and cardiac motion compensation and the ability to display electrogram data on the 3-D shell (activation timing, scar and voltage maps, and dominant frequency). Further development is likely to involve several aspects of the method: automation of the workflow, injection protocols, and software; imaging of cardiac structures other than the LA and development of methods to visualize highly mobile structures such as the ventricles; and integration of anatomical 3-D rotational angiography information with electrogram data.

VIDEOS

The following videos accompany this chapter:

Video 6.1. Focal Atrial Tachycardia (Originating From the Left Atrial Posterior Wall): CARTO Activation and Propagation Maps

Video 6.2. Focal Atrial Tachycardia (Originating From the Inferolateral Tricuspid Annulus): EnSite Precision Activation, Propagation, and Voltage Maps

Electroanatomic (EnSite Precision) activation, propagation, and voltage maps of a focal atrial tachycardia (AT) originating from the inferolateral aspect of the tricuspid annulus (TA). Radiofrequency (RF) ablation at the AT focus results in termination of the tachycardia. *CS*, Coronary sinus; *IVC*, inferior vena cava; *SVC*, superior vena cava.

Video 6.3 Focal Atrial Tachycardia (Originating From the Left Atrial Appendage): EnSite NavX Activation and Propagation Maps. Electroanatomic (EnSite NavX) activation and propagation maps of a focal atrial tachycardia (AT) originating from the left atrial appendage (LAA). Radiofrequency (RF) ablation at the AT focus results in termination of the tachycardia. *LIPV*, Left inferior pulmonary veins; *LSPV*, left superior pulmonary veins; *MA*, mitral annulus; *RIPV*, right inferior pulmonary veins; *RSPV*, right superior pulmonary veins.

Video 6.4 Fast Anatomical Mapping (FAM): CARTO-3. “FAM” is a feature of CARTO-3 that permits rapid creation of anatomical maps by movement of sensor-based catheter throughout the cardiac chamber. In addition, catheters besides the ablation catheter can be visualized (the Lasso [ring], coronary sinus [CS], ablation [ABL], and right ventricular [RV] catheters are visualized in this case). Catheters besides the ablation catheter can be used for data collection. As in this case, the use of the multipolar ring catheter to collect volume data of the left atrial (LA) enhances the mapping speed. The catheter is moved with the LA cavity and pulmonary veins (PVs). *LIPV*, Left inferior PV; *LSPV*, left superior PV; *RIPV*, right inferior PV; *RSPV*, right superior PV.

Video 6.5 CARTO-Sound: Mapping of Ventricular Tachycardia. The CARTO-Sound module is used to construct three-dimensional shell of the LV during mapping and ablation of ventricular tachycardia in a patient with prior anteroapical myocardial infarction. To visualize the LV, the ICE transducer is positioned across the tricuspid valve at the right ventricular septum. The acquired ICE images are gated to the same phase of the cardiac cycles (to the QRS). The LV endocardium is traced manually or automatically. ICE contours can be revisited and revised. The CARTO-Sound volume map of the LV is merged with the electroanatomic shell obtained during voltage mapping. Note the large LV apical scar evident as wall thinning on ICE, which correlates to scar zone (electrogram amplitude less than 0.5 mV; [red] on the voltage map). *ICE*, Intracardiac echocardiography; *LV*, left ventricle.

Video 6.6 Typical Atrial Flutter: Rhythmia Biatrial Propagation Maps. Electroanatomic (Rhythmia) activation and propagation maps of both atria during typical counterclockwise atrial flutter. In the right atrium, the activation wavefront propagates around the tricuspid annulus, consistent with macroreentry. In the left atrium (LA), activation starts at the interatrial septum and CS os, and activation of the whole LA chamber usually comprises only a portion of the tachycardia cycle length. *CS*, Coronary sinus; *LAA*, left atrial appendage; *MA*, mitral annulus; *SVC*, superior vena cava; *TA*, tricuspid annulus.

Video 6.7 Clockwise and Counterclockwise Typical Atrial Flutter: Rhythmia and CARTO Activation and Propagation Maps. Shown are electroanatomic activation and propagation maps of the right atrium during counterclockwise atrial flutter (Rhythmia) and during clockwise atrial flutter (CARTO) in two different patients. CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava; TA, tricuspid annulus.

Video 6.8 Typical Atrial Flutter: EnSite Precision Activation, Voltage, and Propagation Maps. Shown are electroanatomic (EnSite Precision) activation, voltage, and propagation maps of the right atrium during counterclockwise atrial flutter. CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava; TA, tricuspid annulus.

Video 6.9 Electroanatomic Activation Mapping of Typical Atrial Flutter: Effects of the Window of Interest. Shown are two electroanatomic (CARTO) activation maps of the right atrium during counterclockwise atrial flutter (tachycardia cycle length [TCL] = 312 milliseconds) in the same patient. At left, with the window of interest (WOI) set at 300 milliseconds (about 96% of the TCL), the activation map demonstrates a continuous progression of colors around the tricuspid annulus with close proximity of earliest and latest local activation and an activation time in a similar range to TCL, consistent with macroreentry. At right, the WOI is set at 400 milliseconds (which spans more than one tachycardia cycle); this resulted in ambiguous activation map with incoherent activation patterns. CS, Coronary sinus; IVC, inferior vena cava; SVC, superior vena cava; TA, tricuspid annulus.

Video 6.10 Electroanatomic Activation Mapping of Typical Atrial Flutter: Effects of the Electrical Reference. Shown are two electroanatomic (CARTO) activation maps of the right atrium during counterclockwise atrial flutter (tachycardia cycle length [TCL] = 312 milliseconds) in the same patient. At left, with the electrical reference assigned to the electrogram recorded at the low lateral right atrial wall, the early-meets-late zone occurs at the septal aspect of the atrial septum. At right, the electrical reference is assigned to the electrogram recorded at the proximal coronary sinus (CS), and the early-meets-late zone at the lateral right atrial wall. Note that the location of the early-meets-late zone is merely a function of where the offset and onset of the window of interest are defined relative to the timing of the selected reference electrogram, and can shift in location and timing in response to shifts in the window of interest or electrical reference. In addition, early-meets-late zone should not be used as an indicator of the location of the critical isthmus of the macroreentrant circuit or the ablation target (the cavotricuspid isthmus in this case). IVC, Inferior vena cava; SVC, superior vena cava; TA, tricuspid annulus.

Video 6.11 Macroreentrant Atrial Tachycardia (Related to Gaps in Left Atrium [LA] Roof Ablation Line): CARTO Activation and Propagation Maps. Three electroanatomic (CARTO-3) activation maps of the LA acquired during sustained atrial tachycardia (AT) in three different patients with prior history of catheter ablation of atrial fibrillation (circumferential pulmonary vein [PV] isolation and LA roof linear ablation). Propagation and activation maps demonstrate atrial macroreentry involving a gap in the previous LA roof ablation line. LAA, Left atrial appendage; LIPV, left inferior PV; LSPV, left superior PV; MA, mitral annulus; RIPV, right inferior PV; RSPV, right superior PV.

Video 6.12 Macroreentrant Atrial Tachycardia (Involving the Left Atrium [LA] Posterior Wall): Rhythmia Activation and Propagation Maps. Electroanatomic (Rhythmia) activation and propagation maps of the LA acquired during sustained atrial tachycardia (AT) in a patient with prior history of catheter ablation of atrial fibrillation (circumferential antral pulmonary vein [PV] isolation) and electrical isolation of the LA posterior wall (with linear ablation across the LA roof and floor). Propagation and activation maps demonstrate atrial macroreentry involving a gap in the previous LA posterior wall. A few radiofrequency ablation lesions (white dots) transecting the isthmus of the reentry circuit in the LA posterior wall successfully terminate the tachycardia. LIPV, Left inferior PV; LSPV, left superior PV; RIPV, right inferior PV; RSPV, right superior PV.

Video 6.13 Small Atrial Macroreentry: Rhythmia Activation and Propagation Maps. Electroanatomic (Rhythmia) activation and propagation maps of the left atrium (LA) acquired during sustained atrial tachycardia (AT) in a patient with prior history of catheter ablation of atrial fibrillation (circumferential antral pulmonary vein [PV] isolation) and electrical isolation of the LA posterior wall (with linear ablation across the LA roof and floor). Propagation and activation maps demonstrate a small atrial macroreentry circuit involving a gap in the ridge between the LA appendage (LAA) and left-sided PVs. Local electrograms at the isthmus of the reentry circuit are fractionated and occupy a large proportion of the tachycardia cycle length. Radiofrequency (RF) ablation at that site results in termination of the tachycardia. *LIPV*, Left inferior PV; *LSPV*, left superior PV; *MA*, mitral annulus; *RIPV*, right inferior PV; *RSPV*, right superior PV.

Video 6.14 Ripple Mapping: Mapping Gaps in Ablation Line. An electroanatomic (CARTO-3) activation map of the LA (posteroanterior view) acquired during pacing from the mid CS after performing circumferential antral pulmonary vein isolation and electrical isolation of the LA posterior wall (with linear ablation across the LA roof and floor, box lesion). Ablation lesions are shown as red dots. The ripple map is projected over an activation map (*at left*) and over a voltage map (*at right*). The ripple map reveals late activation of the LA posterior wall via a gap in the mid region of the LA roof line. *CS*, Coronary sinus; *LA*, left atrium.

Video 6.15 Electrical Isolation of the Pulmonary Veins and Left Atrial Posterior Wall: Rhythmia Voltage Mapping. Three-dimensional reconstruction of the LA using the Rhythmia electroanatomic system before and after catheter ablation of atrial fibrillation. Small white circles are tagged sites at which RF energy was applied. Circumferential antral PV isolation is performed with a single circumferential ablation lesion around the antrum of the LCPV and separate encircling lesions around the right-sided PVs. Electrical isolation of the LA posterior wall (box isolation) is performed by an ablation line joining the two superior PVs (LA roof line) and a second ablation line joining the two inferior PVs (LA floor line). Sites with voltage lower than 0.1 mV are red on the map, and those with voltage higher than 0.5 mV are purple, with interpolation of color for intermediate amplitudes. The gray area denotes no detectable signal (scar). Note the voltage abatement encompassing all PVs and the whole LA posterior wall within the box lesion. *LA*, Left atrium; *LCPV*, left common pulmonary vein; *PV*, pulmonary vein; *RIPV*, right inferior pulmonary vein; *RSPV*, right superior pulmonary vein.

Video 6.16 Outflow Tract Ventricular Tachycardia: Noncontact Mapping. Mapping of premature ventricular complexes (PVCs) originating from the right ventricular outflow tract (RVOT) using the EnSite 3000 non-contact mapping system. The balloon catheter (*yellow shadow*) is positioned in the RVOT. A detailed geometry of the RVOT is reconstructed by moving a conventional mapping-ablation catheter around the atrium. Color-coded isopotential map of RVOT activation sequence (burning red star surrounded by *white* and *red circles*) during a single PVC is superimposed on the reconstructed three-dimensional shell of the RVOT. Wavefront propagation spreads radially from a small focus. The location of the His bundle is marked (HBE). The inset shows a virtual unipolar electrogram at the site of earliest activation (note QS pattern) with the bar indicating the timing of activation during the PVC. Surface ECG leads and intracardiac contact (ABL) and virtual unipolar electrograms (V_1 - V_4) are shown during mapping of PVCs (*lower panel*). Note the timing of the ABL distal electrogram preceding the onset of the QRS during PVC on all surface ECG leads and coinciding with the downslope of the QS unipolar virtual electrograms.

Video 6.17 Typical Atrial Flutter: Noncontact Mapping. Noncontact mapping (EnSite 3000, St. Jude Medical, St. Paul, MN, United States) during typical atrial flutter (AFL). The multielectrode array surrounding the balloon catheter (*yellow shadow*) is positioned in the center of the atrium and does not come in contact with the atrial walls being mapped. A detailed geometry of the right atrium (RA, shown in *purple*) is reconstructed by moving a conventional mapping-ablation catheter (*red shadow*) around the atrium. RA shell is displayed in right and left anterior oblique (RAO and LAO, respectively) projections. Surface ECG (*white*), contact intracardiac electrograms recorded by the distal and proximal electrodes of the ablation catheter (*red*), and virtual intracardiac electrograms (*yellow*) are shown in the panel in the bottom of the screen, and the yellow vertical line tracks the timing of the activation wavefront displayed on top. Noncontact unipolar electrograms are acquired simultaneously and superimposed onto the virtual endocardium, producing isopotential maps with a color range representing voltage amplitude. **Part 1:** During counter-clockwise typical AFL, wavefront activation sequence is tracked on the isopotential map throughout the tachycardia cycle (burning red star surrounded by *white* and *red circles*). **Part 2:** Before ablation of the cavotricuspid isthmus (CTI), atrial pacing from the medial aspect of the CTI results in two wavefronts: one propagating up the septum and a second propagating across the CTI (viewed clearly in the RAO projection). The two wavefronts converge in the lateral RA wall. This indicates intact conduction through the CTI in the clockwise direction. Note that an initial white activation artifact is caused by the pacing stimulus saturation artifact and precedes the activation wavefront through the RA. **Part 3:** After successful ablation of the CTI (indicated by the *pink dots* across the CTI), atrial pacing from the medial aspect of the CTI results in a single wavefront that propagates cranially up the septum and caudally down the RA free wall in a counterclockwise direction around the tricuspid annulus. No conduction is observed via the CTI, suggesting clockwise block in the CTI. **Part 4:** After successful ablation of the CTI, atrial pacing from the lateral aspect of the CTI results in a single wavefront that propagates cranially up RA free wall and caudally down the septum the in a clockwise direction around the tricuspid annulus. No conduction is observed via the CTI, suggesting counterclockwise block in the CTI.

Video 6.18 Intracardiac Echocardiography: Home View. The “home view” obtained by the intracardiac echocardiography (ICE) catheter. Initially, the catheter is positioned in the mid-right atrium (RA) with the catheter tension controls in neutral position (the ultrasound transducer oriented anteriorly and to the left), the RA, tricuspid valve (TV), and right ventricle (RV) are viewed. Gradual clockwise rotation of a straight catheter from the home view allows sequential visualization of the aortic root and aortic valve (AoV), followed by the coronary sinus (CS) and the left atrium (LA), and a cross-sectional view of the interatrial septum.

Video 6.19 Intracardiac Echocardiography Imaging of the Left Ventricle and Aortic Valve. The “home view” obtained by the ICE catheter. Initially, the catheter is positioned in the mid RA with the catheter tension controls in neutral position (the ultrasound transducer oriented anteriorly and to the left), the RA, TV, and RV are viewed. Gradual clockwise rotation of a straight catheter from the home view allows sequential visualization of the AO and AoV, followed by the LA, and a cross-sectional view of the interatrial septum. From that point, forward flexion of the ICE catheter into the RV brings the LV and MV in view. Slight counter-clockwise rotation (while maintaining forward flexion) of the ICE catheter enables cross sectional imaging of the AoV. Ao, Aortic root; AoV, aortic valve; ICE, intracardiac echocardiography; LA, left atrium; LAA, left atrial appendage; LV, left ventricle; RA, right atrium; RV, right ventricle; RVOT, right ventricular outflow tract; TV, tricuspid valve.

Video 6.20 Intracardiac Echocardiography for Visualization of the Papillary Muscle. The ICE catheter is advanced to the right atrium then flexed across the tricuspid valve and positioned at the RV septum. A longitudinal view of the LV is obtained, and the ablation catheter can be seen in contract with the lateral papillary muscle. ICE, Intracardiac echocardiography; LV, left ventricle; RV, right ventricle.

Video 6.21 CARTO-Sound: Ablation of Atrial Fibrillation. The CARTO-Sound utilizes a phased-array intracardiac echocardiography (ICE) catheter with an embedded navigation sensor (SoundStar, Biosense Webster), which records individual 90-degree sector image planes of the cardiac chamber, including their location and orientation, to the CARTO workspace. **Part 1:** ICE images are acquired before atrial septal puncture and are gated to the same phase of the cardiac cycles (to the QRS). The endocardial surfaces of the left atrium (LA) and pulmonary veins (PVs) are traced manually. A three-dimensional (3-D) geometry of the LA and PVs is reconstructed by interpolation of points the traced endocardial surface from multiple ICE images. **Part 2:** ICE images are acquired after access to the LA. A transseptal sheath can be visualized in the LA. LA endocardial surface can be traced automatically. However, verification of traced endocardial surfaces is required. In this case, the transseptal sheath was erroneously marked as an endocardial surface, and manual overwriting is required. **Part 3:** The ICE probe can be advanced into the LA across the atrial septum to obtain higher quality images of the endocardial border of the LA and PVs. **Part 4:** A 3-D geometry of the LA and PVs is reconstructed by interpolation of points the traced endocardial surface from multiple ICE images. The CARTO-Sound volume map of the cardiac chamber can be used as a stand-alone tool to guide navigation and ablation. **Part 5:** All contours can be revisited and revised.

Video 6.22 Cardiac Anatomy (Segmented Computed Tomography). Ao, Aorta; IVC, inferior vena cava; LAA, left atrial appendage; LIPV, left inferior pulmonary vein; LPA, left pulmonary artery; LSPV, left superior pulmonary vein; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RIPV, right inferior pulmonary vein; RPA, right pulmonary artery; RV, right ventricle; RSPV, right superior pulmonary vein; SVC, superior vena cava.

Video 6.23 Segmented Computed Tomography of the Left Atrium and Pulmonary Veins (PVs). LAA, Left atrial appendage; LIPV, left inferior PV; LSPV, left superior PV; RIPV, right inferior PV; RSPV, right superior PV.

RADIOFREQUENCY ABLATION

Biophysics of Radiofrequency Energy

Radiofrequency (RF) refers to the portion of the electromagnetic spectrum in which electromagnetic waves can be generated by alternating current (AC) fed to an antenna. Electrosurgery (coagulation, cauterization, and ablation) currently uses hectomeric wavelengths found in band 6 (300 to 3000 kHz), which are similar to those used for broadcast radio. However, the RF energy is electrically conducted, not radiated, during catheter ablation. The RF current is similar to low-frequency AC or direct current (DC) with regard to its ability to heat tissue and create a lesion, but it oscillates so rapidly that cardiac and skeletal muscles are not stimulated, thereby avoiding induction of arrhythmias and decreasing the pain perceived by the patient. RF current rarely induces rapid polymorphic arrhythmias; such arrhythmias can, however, be observed in response to low-frequency (60-Hz) stimulation. Frequencies higher than 1000 kHz are also effective in generating tissue heating; however, such high frequencies are associated with considerable energy loss along the transmission line. Therefore frequencies of the RF current commonly used are in the range of 300 to 1000 kHz, a range that optimizes efficacy and safety.

Radiofrequency Energy Delivery

Delivery of RF energy depends on the establishment of an electrical circuit involving the human body as one of its in-series elements. The RF current is applied to the tissue via a metal electrode at the tip of the ablation catheter and is generally delivered in a unipolar fashion between the tip electrode and a ground pad applied to the patient's skin. Bipolar RF systems also exist, in which the current flows between

two closely apposed small electrodes, thus limiting the current flow to small tissue volumes interposed between the metal conductors. Bipolar systems, partly because of their relative safety, are now the preferred tools in electrosurgery (oncology, plastic surgery, and ophthalmology), and have been increasingly utilized for catheter ablation of cardiac arrhythmias.

Unipolar RF systems. Unipolar systems apply RF energy between the ablation catheter tip electrode and a large dispersive electrode (indifferent electrode, or ground pad) applied to the patient's skin. The polarity of connections from the electrodes to the generator is not important because the RF current is an AC. The system impedance comprises the impedance of the generator, transmission lines, catheter, electrode-tissue interface, dispersive electrode-skin interface, and interposed tissues. As electricity flows through a circuit, every point of that circuit represents a drop in voltage, and some energy is dissipated as heat. The point of greatest drop in line voltage represents the area of highest impedance and is where most of the electrical energy becomes dissipated as heat. Therefore with excessive electrical resistance in the transmission line, the line actually warms up and power is lost. Currently used electrical conductors from the generator all the way through to the patient and from the dispersive electrode back to the generator have low impedance, to minimize power loss.

Flow of the RF current from the ablation electrode through the myocardium to the indifferent electrode results in resistive tissue heating and lesion formation. With normal electrode-tissue contact, only a fraction of all power is effectively applied to the tissue. The rest is dissipated in the blood pool and elsewhere in the patient. With an ablation electrode in contact with the endocardial wall, part of the electrode contacts tissue and the rest contacts blood, and the RF current flows

through both the myocardium and the blood pool surrounding the electrode. The distribution between both depends on the impedance of both routes and also on how much electrode surface contacts blood versus endocardial wall. Whereas tissue heating is the goal of power delivery, the blood pool is the most attractive route for RF current because blood is a better conductor and has significantly lower impedance than tissue and because the contact between electrode and blood is often better than with tissue. Therefore with normal electrode-tissue contact, much more power is generally delivered to blood than to cardiac tissue.

After leaving the electrode-blood-tissue interface, the current flows through the thorax to the ground pad. Part of the RF power is lost in the patient's body, including the area near the ground pad. However, because the surface area of the ablation electrode (approximately 12 mm²) is much smaller than that of the dispersive electrode (approximately 100 to 250 cm²), the current density is higher in the immediate vicinity of the ablation electrode, and heating occurs preferentially at that site, with no significant heating occurring at the dispersive electrode. Nonetheless, when RF energy delivery is power-limited, dissipation of energy can occur at the dispersive electrode site (at the contact point between the ground pad and the skin) to a degree that can limit lesion formation at the ablation electrode.¹

The dispersive electrode may be placed on any convenient skin surface. The geometry of the RF current field is defined by the geometry of the ablation electrode and is relatively uniform in the region of volume heating. Thus, the position of the dispersive electrode (on the patient's back or thigh) has little effect on impedance, voltage, current delivery, catheter tip temperature, or geometry of the resulting lesion. The size of the dispersive electrode, however, is important. Sometimes it is advantageous to increase the surface area of the dispersive electrode. This increase leads to lower impedance, higher current delivery, increased catheter tip temperatures, and more effective tissue heating. This is especially true in patients with baseline system impedance greater than 100 Ω . Moreover, when the system is power limited, as with a 50-W generator, heat production at the catheter tip varies with the proportion of the local electrode-tissue interface impedance to the overall system impedance. If the impedance at the skin-dispersive electrode interface is high, then a smaller amount of energy is available for tissue heating at the electrode tip. Therefore when ablating certain sites, adding a second dispersive electrode or optimizing the contact between the dispersive electrode and skin should result in relatively more power delivery to the target tissue. In addition, meticulous skin preparation is imperative to optimize skin-patch contact and minimize impedance at the skin interface with the dispersive electrode.¹

A large surface area, and good skin contact, is required at the indifferent electrode patch not only to effectively dissipate heat but also to prevent skin burns. The skin temperature beneath the patch is inversely proportional to patch surface area in contact with the skin and the distance between the patch and the active electrode. If ablation is performed with a high-amplitude current (more than 50 W) and skin contact by the dispersive electrode is poor, skin temperatures can potentially rise above 45°C which, even when short lasting, can result in significant skin burns, especially at the "leading edge" of the patch (the side closest to the RF catheter electrode) (eFig. 7.1).¹

Bipolar RF systems. Bipolar RF ablation uses two adjacent ablation electrodes between which the RF flows, leading to lesion formation between electrodes. Although used in cardiac surgery, bipolar RF ablation has not been widely adopted as a catheter-based treatment for clinical arrhythmias.

Recent studies have demonstrated that bipolar RF ablation using two ablation catheter tips (at opposite sides of the myocardial wall) as the active and ground poles, can potentially create deeper, transmural

Fig. 7.1 Bipolar Versus Sequential Unipolar Radiofrequency Ablation. Representative image of gross lesion following ablation with (A) sequential unipolar lesion showing nontransmural lesion (tissue thickness of 16.6 mm) and (B) bipolar lesion showing a transmural lesion (tissue thickness of 19 mm). (From Koruth JS, Dukkupati S, Miller MA, et al. Bipolar irrigated radiofrequency ablation: a therapeutic option for refractory intramural atrial and ventricular tachycardia circuits. *Heart Rhythm*. 2012;9:1932–1941.)

lesions (Fig. 7.1). Simultaneous tissue heating and increased current density result in the concentration of thermal injury within the zone between the two closely spaced ablation electrodes and improve efficacy of ablation, as compared with sequential or even simultaneous unipolar RF ablation.² In one report, transmural lesions with bipolar RF ablation could be realized in tissues as thick as 25 mm, in contrast to sequential unipolar RF, which was unable to achieve transmural lesions when thicknesses are greater than 15 mm. This can offer a significant advantage for ablation of septal atrial tachycardia (AT) or ventricular tachycardia (VT) circuits (with one ablation catheter positioned on one side of the septum and the second catheter positioned at the opposite side, Fig. 7.2) or intramural free wall VT circuits (with one ablation catheter positioned endocardially and the second catheter positioned epicardially).^{2,3}

In another design, bipolar RF ablation is used to create contiguous lesions between adjacent electrodes mounted on a multielectrode ablation catheter positioned at one side of the myocardial wall. A multi-channel duty-cycled RF ablation generator (GENius MultiChannel RF Generator, Medtronic, Minneapolis, MN, United States) contains 12 independently controlled RF generators, and is capable of delivering RF energy to each electrode independently. RF energy can be delivered in either bipolar (between the electrodes) and unipolar (from the electrode to the ground pad) current by a phase difference between the channels (thus the term, "phased RF"). During unipolar ablation, current flow is provided between the electrodes and an indifferent electrode attached to the patient's skin, while in the bipolar energy mode, current flows between adjacent electrodes. In this design, bipolar RF ablation lesions are longer, but shallower than unipolar RF lesions. To improve lesion depth, RF energy can also be delivered in a unipolar mode from each electrode to a dispersive electrode.^{4–6}

A second atrial fibrillation (AF) ablation system (nMARQ, Biosense Webster, Diamond Bar, CA, United States) employs a multichannel RF generator capable of independently delivering unipolar or bipolar RF energy to a maximum of 10 electrodes simultaneously. The nMARQ catheter is a decapolar mapping and ablation catheter with individually

eFig. 7.1 Second-Degree Skin Burns at the Site of Ablation Ground Pad Contact. Skin burns occurred on the patient's thigh secondary to poor contact between the skin and the ground pad during radiofrequency ablation of atrial fibrillation.

(C and D) Fluoroscopic views of catheter positions on either side of the septum at the site of successful termination of ventricular tachycardia. (From Koruth JS, Dukkipati S, Miller MA, et al. Bipolar irrigated radiofrequency ablation: a therapeutic option for refractory intramural atrial and ventricular tachycardia circuits. *Heart Rhythm*. 2012;9:1932–1941.)

irrigated platinum electrodes. Each electrode possesses a thermocouple and holes for irrigation. RF energy is applied in a temperature-controlled mode and energy delivery can be individually arranged over each combination of the 10 electrodes in unipolar mode or bipolar mode between two adjacent electrodes.^{7–9}

Tissue Heating

While free electrons serve as charge carriers inside the RF generator, cables, and RF electrode, the electric current inside tissue is carried by charged ions (such as Na^+ , K^+ , and Cl^-). During AC flow, charged carriers in tissue (ions) attempt to follow the changes in the direction of the AC. For a typical frequency of 500 kHz, the direction of the current (and ion movement) changes a million times per second. Ion oscillations generate heat due to friction, thus converting electromagnetic (current) energy into molecular mechanical energy or heat. This type of electric current-mediated heating is known as ohmic (resistive) heating. Using Ohm's law, with resistive heating, the amount of power (= heat) per unit volume equals the square of current density times the specific impedance of the tissue. With a spherical ablation electrode, the current flows outward radially, and current density therefore decreases with the square of distance from the center of the electrode. As a consequence, power dissipation per unit volume decreases with the fourth power of distance. The thickness of the electrode eliminates the first

steepest part of this curve, however, and the decrease in dissipated power with distance is therefore somewhat less dramatic.

Approximately 90% of all RF power that is delivered to the tissue is absorbed within the first 1 to 1.5 mm from the ablation electrode surface. Therefore only a thin rim of tissue in immediate contact with the RF electrode is directly heated (within the first 2 mm of depth from the electrode). The remainder of tissue heating occurs as a result of heat conduction from this rim to the surrounding tissues. On initiation of fixed-level energy application, the temperature at the electrode-tissue interface rises monoexponentially to reach steady state within 7 to 10 seconds, and the steady state is usually maintained between 80°C and 90°C. However, whereas resistive heating starts immediately with the delivery of RF current, conduction of heat to deeper tissue sites is relatively slow and requires 1 to 2 minutes to equilibrate (thermal equilibrium). Therefore the rate of tissue temperature rise beyond the immediate vicinity of the RF electrode is much slower, resulting in a steep radial temperature gradient as tissue temperature decreases radially in proportion to the distance from the ablation electrode, and deep tissue temperatures continue to rise for several seconds after interruption of RF delivery (the so-called thermal latency phenomenon). Therefore RF ablation requires at least 30 to 60 seconds to create full-grown lesions. In addition, when temperature differences between adjacent areas develop because of differences in local current density or local heat capacity,

heat conducts from hotter to colder areas, thus causing the temperature of the former to decrease and that of the latter to increase. Furthermore, heat loss to the blood pool at the surface and to intramyocardial blood vessels determines the temperature profile within the tissue.

At steady state, the lesion size is proportional to the temperature measured at the interface between the tissue and the electrode, as well as to the RF power amplitude. By using higher powers and achieving higher tissue temperatures, the lesion size can be increased. Tissue temperatures of up to 110°C can be achieved. Above this temperature, tissue vaporization ensues and prevents any further heating by RF current due to the electrically insulating properties of vapor. Also, boiling of the plasma at the electrode-tissue interface can cause tissue carbonization (“charring”) at the site of very high RF current densities (typically very close to the RF electrode), producing an electrically insulating coagulum, which is accompanied by a sudden increase in electrical impedance that prevents further current flow into the tissue and further heating.

The range of desired tissue temperatures during RF ablation is 50°C to 90°C. Within this range, relatively uniform desiccation of tissue can be expected. If the temperature is lower than 50°C, no or only minimal tissue necrosis results. Temperatures above 100°C are associated with tissue vaporization, including steam pops, and charring. Because the rate of temperature rise at deeper sites within the myocardium is slow, a continuous energy delivery of at least 60 seconds is often warranted to maximize depth of lesion formation.

Convective Cooling

At the site of endocardial ablation, tissues heated directly by RF energy start losing heat into deeper layers of myocardium as well as into the circulating blood pool and the metal ablation electrode (Fig. 7.3). Heat conduction into deeper myocardial layers helps increase the size of the ablation lesion. Heat conduction to the ablation electrode helps indirect monitoring of tissue temperature via the embedded temperature sensors. On the other hand, convective heat loss from the endocardium at the site of ablation into the circulating blood pool results in cooling of the endocardial surface, and constitutes the dominant factor opposing

effective myocardial heating and lesion formation. Because the tissue surface is cooled by the blood flow, the highest temperature during RF delivery occurs slightly below the endocardial surface. Consequently, the width of the endocardial lesion matures earlier than the intramural lesion width (20 seconds vs. 90 to 120 seconds). Hence, the maximum lesion width is usually located intramurally, and the resultant lesion is usually teardrop shaped, with less necrosis of the superficial tissue.

As the magnitude of convective cooling increases (e.g., unstable catheter position, poor catheter-tissue contact, or high blood flow in the region of catheter position), there is decreased efficiency of heating as more energy is carried away in the blood and less energy is delivered to the tissue. When RF power is limited and insufficient to overcome the heat lost by convection, lesion size is reduced. On the other hand, when RF power delivery is not limited, convective cooling allows for more power to be delivered into the tissue (as long as adequate electrode-tissue contact is maintained), increasing the depth of direct resistive heating and intramural tissue temperatures (and hence larger ablation lesion size), while avoiding very high endocardial surface temperatures (and temperatures measured by the catheter tip sensors) that can otherwise result in blood boiling and coagulum formation at the electrode tip, with consequent sudden rise in electrical impedance and reduction of further power delivery.

The concept of convective cooling can explain why there are few coronary arterial complications with conventional RF ablation. Coronary arteries act as a heat sink; substantive heating of vascular endothelium is generally prevented by heat dissipation in the high-velocity coronary blood flow, even when the catheter is positioned close to the vessel. Although this is advantageous, because coronary arteries are being protected, it can limit success of the ablation lesion if a large perforating artery is close to the ablation target and can protect the target tissue from ablation by transferring heat away from it.¹⁰

The effects of convective cooling have been exploited to increase the size of catheter ablative lesions. Active electrode cooling by ablation electrode irrigation is currently used to largely eliminate the risk of overheating at the electrode-tissue contact point and increase the magnitude of power delivery and the depth of volume heating.

Of note, standard RF ablation is not as effective when delivered to the epicardium compared with lesions delivered to the endocardium for a number of reasons, one of which is the lack of convective cooling (by the circulating blood) of the ablation electrode in the epicardial space. This results in high electrode temperatures at low-power settings (≤ 10 W), limiting power delivery in the pericardial space and hindering lesion formation. Therefore active electrode cooling is required in this setting.¹¹

Catheter Tip Temperature

Ablation catheter tip temperature depends on tissue temperature, tissue contact of the ablation electrode, convective cooling by the surrounding blood, heat capacity of the electrode material, and type and location of the temperature sensor.

Catheter tip temperature is measured by a sensor located in the ablation electrode. There are two different types of temperature sensors: thermistors and thermocouples. Thermistors require a driving current, and the electrical resistance changes as the temperature of the electrical conductor changes. More frequently used are thermocouples, which consist of copper and constantan wires and are incorporated in the center of the ablation electrode. Thermocouples are based on the so-called “Seebeck effect”; when two different metals are connected (sensing junction), a voltage can be measured at the reference junction that is proportional to the temperature difference between the two metals.

The electrode temperature rise is an indirect process—the ablation electrode is not heated by RF energy, but it heats up because it happens

Fig. 7.3 Biophysics of Radiofrequency Heating. This illustration represents the regions of resistive and conductive heating of tissue, and convective heat loss from tissue into the circulating blood pool and epicardial coronary arteries when delivering radiofrequency current to the endocardium using a conventional 4-mm-tip electrode catheter. (From Houmsse M, Daoud EG. Biophysics and clinical utility of irrigated-tip radiofrequency catheter ablation. *Expert Rev Med Devices*. 2012;9: 59–70.)

to touch heated tissue. Consequently, the catheter tip temperature is always lower than, or ideally equal to, the superficial tissue temperature. Conventional electrode catheters with temperature monitoring report the temperature only from the center of the electrode mass with one design, or from the apex of the tip of the catheter with another design. It is likely that the measured temperature underestimates the peak tissue temperature (which occurs slightly below the endocardial surface).

Several other factors can increase the disparity between catheter tip temperature and tissue temperature, including catheter tip irrigation, large ablation electrode size, and poor electrode-tissue contact. Catheter tip irrigation increases the disparity between tissue temperature and electrode temperature because it results in cooling of the ablation electrode, but not the tissue. With a large electrode tip, a larger area of the electrode tip is exposed to the cooling effects of the blood flow than with standard tip lengths, thus resulting in lower electrode temperatures. Similarly, with poor electrode-tissue contact, less electrode material is in contact with the tissue, and heating of the tip by the tissue occurs at a lower rate, resulting in relatively low tip temperatures.

Biophysics of Cooled Radiofrequency Ablation

There are two methods of active electrode cooling by irrigation: internal and external (Fig. 7.4). With the internal (closed-loop) system (Chilli, Boston Scientific, Natick, MA), cooling of the ablation electrode is achieved by circulating fluid within the electrode. In contrast, with the external (open-loop) system (Celsius or Navistar ThermoCool, Biosense Webster, Diamond Bar, CA, United States; and Therapy Cool Path, St. Jude Medical, St. Paul, MN, United States), electrode cooling is performed by flushing saline through openings in the porous-tipped electrode (showerhead-type system). Another cooling system is sheath-based open irrigation, which uses a long sheath around the ablation catheter for open irrigation. The latter system was found to provide the best results, but this type of catheter tip cooling is not clinically available.

Active electrode cooling by irrigation can produce higher tissue temperatures and create larger lesions, compared with standard RF

ablation catheters, because of a reduction in overheating at the tissue-electrode interface, even at sites with low blood flow. This allows the delivery of higher amounts of RF power for a longer duration to create relatively large lesions with greater depth but without the risk of coagulum and char formation. Unlike with standard RF ablation, the area of maximum temperature with cooled ablation is within the myocardium, rather than at or just below the electrode-myocardial interface. Higher power results in greater depth of volume heating, but if the ablation is power limited, power dissipation into the circulating blood pool can actually result in decreased lesion depth (Fig. 7.5). Compared with large-tip catheters, active cooling has been shown to produce equivalent lesions with energy delivery via smaller irrigated electrodes, with less dependence on catheter tip orientation and extrinsic cooling, whereas larger electrodes have significant variability in their electrode-tissue interface, depending on catheter orientation (see Fig. 7.5). For the nonirrigated catheter, greater lesion volumes are observed with a horizontal orientation of the RF electrode compared with a vertical orientation. In contrast, for irrigated catheters, lesion volume increased with a perpendicular electrode orientation compared with the horizontal orientation.

Lesion depth seems to be similar between closed-loop and open-irrigation electrodes. However, open irrigation is more effective in cooling the electrode-tissue interface, as reflected by lower interface temperature, lower incidence of thrombus, and smaller lesion diameter at the surface (with the maximum diameter produced deeper in the tissue). These differences between the two electrodes are greater in low blood flow, presumably because the flow of saline irrigation out of the electrode provides additional cooling of the electrode-tissue interface (external cooling). Ablation with internal electrode cooling in low blood flow regions frequently results in high electrode-tissue interface temperature (despite low electrode temperature) and coagulum formation.¹²

When maximum power and temperature parameters that did not result in any evidence of excessive heating (including popping, boiling, or impedance rise) for each catheter type were selected, closed-irrigation

Fig. 7.4 Schematic Representation of Irrigated Electrode Catheters. (A) The closed-loop irrigation catheter has a 7 Fr, 4-mm-tip electrode with an internal thermocouple. (B) The open-irrigated catheter has a 7.5 Fr, 3.5-mm-tip electrode with an internal thermocouple and six irrigation holes (0.4-mm diameter) located around the electrode, 1.0 mm from the tip. NaCl, Sodium chloride. (From Yokoyama K, Nakagawa H, Wittkamp FH, et al. Comparison of electrode cooling between internal and open irrigation in radiofrequency ablation lesion depth and incidence of thrombus and steam pop. *Circulation*. 2006;113:11.)

Fig. 7.5 Effect of Electrode Type on Lesion Size. Representative blocks of myocardium are shown with lesions (*dark shading*) resulting from optimal radiofrequency energy delivery for each electrode type. A 4-mm electrode makes a small shallow lesion (*left*). An 8-mm electrode makes a larger, deeper lesion (*center*). The open-irrigated electrode makes a larger, deeper lesion, with a maximum width at some tissue depth (*right*).

catheters resulted in slightly larger lesion volumes and greater lesion depths than the open-irrigation catheters. Both cooled catheters fared better than the standard 4-mm-tip and large 10-mm-tip catheters with larger lesions achieved within the range of safe energy delivery.

Pathophysiology of Radiofrequency Lesion Formation

Cellular Effects of Radiofrequency Ablation

The primary mechanism of tissue injury by RF ablation is likely to be thermally mediated. Hyperthermic injury to the myocyte is both time- and temperature-dependent, and it is likely the result of changes in the cell membrane, protein inactivation, cytoskeletal disruption, nuclear degeneration, as well as other potential mechanisms. The cell membrane, in particular, is very sensitive to thermal injury. Hyperthermia results in potential phase change in membrane fluidity, kinetic and structural changes in membrane ion channels and ion pumps, inhibition of transport proteins, and formation of nonspecific ionic membrane pores.

Experimentally, the resting membrane depolarization is related to temperature. In the low hyperthermic range (37°C to 45°C), little tissue injury occurs, and a minor change can be observed in the resting membrane potential and action potential amplitude. However, action potential duration shortens significantly, and conduction velocity becomes greater than at baseline. In the intermediate hyperthermic range (45°C to 50°C), progressive depolarization of the resting membrane potential occurs, and action potential amplitude decreases. In addition, abnormal automaticity is observed, reversible loss of excitability develops, and conduction velocity progressively decreases. In the high temperature ranges (higher than 50°C), marked depolarization of the resting membrane potential occurs, and permanent loss of excitability is observed. Temporary (at temperatures of 49.5°C to 51.5°C) and then permanent (at 51.7°C to 54.4°C) conduction block develops, and fairly reliable irreversible myocardial injury occurs with a short hyperthermic exposure.

In the clinical setting, the success of ablation is related to the mean temperature measured at the electrode-tissue interface. Block of conduction in an atrioventricular (AV) bypass tract (BT) usually occurs at 62°C \pm 15°C. During ablation of the AV junction, an accelerated junctional rhythm, which is probably caused by thermally or electrically induced

cellular automaticity or triggered activity, is observed at temperatures of 51°C \pm 4°C, whereas reversible complete AV block occurs at 58°C \pm 6°C, and irreversible complete AV block occurs at 60°C \pm 7°C.

RF ablation typically results in high temperatures (70°C to 90°C) for a short time (up to 60 seconds) at the electrode-tissue interface, but significantly lower temperatures at deeper tissue sites. This leads to rapid tissue injury within the immediate vicinity of the RF electrode but relatively delayed myocardial injury with increasing distance from the RF electrode. Therefore, although irreversible loss of electrophysiological (EP) function can usually be demonstrated immediately after successful RF ablation, this finding can be delayed because tissue temperatures continue to rise somewhat after cessation of RF energy delivery (thermal latency phenomenon). This effect can account for the observation that patients undergoing atrioventricular node (AVN) modification procedures who demonstrate transient heart block during RF energy delivery can progress to persisting complete heart block, even if RF energy delivery is terminated immediately. Reversible loss of conduction can be demonstrated within seconds of initiating the RF application, which can be caused by an acute electrotonic effect. On the other hand, there can be late recovery of EP function after an initial successful ablation.

In addition to the dominant thermal effects of RF ablation, some of the cellular injury has been hypothesized to be caused by a direct electrical effect, which can result in dielectric breakdown of the sarcolemmal membrane with creation of transmembrane pores (electroporation), resulting in nonspecific ion transit, cellular depolarization, calcium overload, and cell death. Such an effect has been demonstrated with the use of high-voltage electrical current. However, it is difficult to examine the purely electrical effects in isolation of the dominant thermal injury.

Tissue Effects of Radiofrequency Ablation

Changes in myocardial tissue are apparent immediately on completion of the RF lesion. Pallor of the central zone of the lesion is attributable to denaturation of myocyte proteins (principally myoglobin) and subsequent loss of the red pigmentation. Slight deformation, indicating volume loss, occurs at the point of catheter contact in the central region of lesion formation. The endocardial surface is usually covered with a thin fibrin layer and, occasionally, if a temperature of 100°C has been exceeded, with char and thrombus (eFig. 7.2). In addition, a coagulum (an accumulation of fibrin, platelets, and other blood and tissue components) can form at the ablation electrode because of the boiling of blood and tissue serum.

On sectioning, the central portion of the RF ablation lesion shows desiccation, with a surrounding region of hemorrhagic tissue and then normal-appearing tissue. Histological examination of an acute lesion shows typical coagulation necrosis with basophilic stippling consistent with intracellular calcium overload. Immediately surrounding the central lesion is a region of hemorrhage and acute monocellular and neutrophilic inflammation.

The progressive changes seen in the evolution of an RF lesion are typical of healing after any acute injury. Within 2 months of the ablation, the lesion shows fibrosis, granulation tissue, chronic inflammatory infiltrates, and significant volume contraction. The lesion border is well demarcated from the surrounding viable myocardium without evidence of a transitional zone. This likely accounts for the absence of proarrhythmic side effects of RF catheter ablation. As noted, because of the high-velocity blood flow within the epicardial coronary arteries, these vessels are continuously cooled and are typically spared from injury, despite nearby delivery of RF energy. Nonetheless, high RF power delivery in small hearts, such as in pediatric patients, or in direct contact with the vessel can potentially cause coronary arterial injury.¹⁰

eFig. 7.2 Standard Radiofrequency Ablation Catheter With Char Formed on the Tip.

The border zone around the acute pathological RF lesion accounts for several phenomena observed clinically. The border zone is characterized by marked ultrastructural abnormalities of the microvasculature and myocytes acutely, as well as a typical inflammatory response later. The most thermally sensitive structures appear to be the plasma membrane and gap junctions, which show morphological changes as far as 6 mm from the edge of the pathological lesion. The border zone accounts for documented effects of RF lesion formation well beyond the acute pathological lesion. The progression of the EP effects after completion of the ablation procedure can be caused by further inflammatory injury and necrosis in the border zone region that result in late progression of physiological block and a delayed cure in some cases. On the other hand, initial stunning and then early or late recovery of function can be demonstrated in the border zone, thus accounting for the recovery of EP function after successful catheter ablation in the clinical setting, which can be caused by healing of the damaged, but surviving, myocardium.

Coagulum Formation

Excessive tissue heating can lead to high temperatures at the electrode-tissue interface. Once the peak tissue temperature exceeds the threshold of 100°C, boiling of blood and tissue serum at the electrode-tissue interface can ensue. When boiling occurs, denatured serum proteins and charred tissue form a thin film that adheres to the electrode, thus producing an electrically insulating coagulum (an accumulation of fibrin, platelets, and other blood and tissue components). The coagulum can detach and embolize. Of note, unlike typical thrombi, a coagulum is not formed by activation of clotting factors, and its formation is not prevented by anticoagulation.

In temperature-controlled RF ablation, electrode temperature does not reach the boiling point. Nonetheless, the true tissue temperature can be significantly higher than the measured electrode temperature. In addition, serum proteins denature at temperatures well below the interfacial boiling temperature. Therefore coagulum can still form even when the electrode temperature is limited to 65°C with a 4-mm ablation electrode, and 55°C with an 8-mm electrode. Open irrigation cools the electrode and its direct environment (blood, and catheter-tissue interface), reducing (but not eliminating) the risk of interfacial boiling and coagulum formation. Also, the irrigant helps wash away denatured proteins as it forms.¹³

Usually, coagulum adheres to the electrode tip, which is accompanied by a sudden increase in electrical impedance that prevents further current flow into the tissue and further heating, at which point the ablation catheter needs to be withdrawn from the body and cleaned to remove the adhering coagulum. However, when the coagulum attaches to the tissue surface rather than to the electrode tip, electrode temperature or impedance may not be affected, and coagulum formation can continue unnoticed. Therefore the absence of impedance rise during ablation does not guarantee the absence of coagulum formation on the tissue contact site.

Steam Pop

High RF power application (especially in the setting of cooled RF ablation) can cause superheating within the tissue (with subendocardial tissue temperatures exceeding 100°C), which can result in boiling of water within the tissue under the electrode. Consequently, evaporation and rapid steam expansion can occur intramurally, and a gas bubble can develop in the tissue under the ablation electrode. Continued application of RF energy causes the bubble to expand and its pressure to increase, which can lead to eruption of the gas bubble (causing a popping sound) through the path with the least mechanical resistance that can leave behind a gaping hole (the so-called “steam pop”). This often occurs

toward the heat-damaged endocardial surface (leading to crater formation) or, infrequently, across the myocardial wall (resulting in myocardial perforation).

The consequence of a steam pop depends on the area of the heart being ablated. The risk of cardiac perforation is low in areas of dense ventricular scar. The risk of perforation and cardiac tamponade is likely to be higher for ablation in the thin-walled right ventricular outflow tract (RVOT) and in the atria. Therefore it is reasonable to take a more conservative approach to power application in these areas.

Steam pops are often associated with a sudden, although small (less than 10 Ω) impedance rise and a sudden drop in electrode temperature. When steam pops burst toward the endocardial surface, a shower of microbubbles is often detected on intracardiac echocardiography (ICE).

The risk of steam pops is relatively low with temperature-controlled standard 4-mm-tip RF catheter ablation, since the electrode temperature, which approximates tissue temperature, is limited to a safe level. However, when there is significant discrepancy between tissue and electrode temperature, due to passive or active electrode cooling, tissue temperature can reach the boiling point without being detected by the monitoring electrode temperature.

Electrode orientation also seems to affect the significance of steam pops; pops that occur when the electrode tip is perpendicular to the tissue are more likely to cause cardiac perforation than those that occur when the electrode is lying horizontally on the tissue. Therefore one should try to avoid high-pressure perpendicular tissue contact, especially at higher RF power outputs. RF applications preceding steam pops have a greater and more rapid decrease in impedance and occur at a higher maximum RF power than applications without pops. Because of the considerable overlap of impedance changes in lesions with and without steam pops, it is not possible to advocate a general limit for impedance decrease for all RF lesions. However, when ablation is performed in areas at risk for perforation (i.e., especially in thin-walled structures), reducing power to achieve an impedance decrease of less than 18 Ω is a reasonable strategy to reduce the chance of a pop.

Determinants of Radiofrequency Lesion Size

It is axiomatic that successful ablation occurs when an adequate amount of ablation energy is delivered for an adequate amount of time, with adequate electrode-tissue contact, at an appropriate target site. Many of the elements of this statement relate to formation of an effective ablation lesion. Lesion size is defined as the total volume or dimensions (width and depth) of the lesion. The size of the lesion created by RF power is determined by the amount of tissue heated to more than the critical temperature for producing irreversible myocardial damage (50°C). Tissue heating is a function of the magnitude of RF power that is converted into heat in the tissues. As noted, only a thin rim (1 to 2 mm) of tissue immediately under the ablating electrode is directly heated. This heat then radiates to adjacent tissue; however, conduction of heat to deeper tissue sites is relatively slow and very inefficient. The distance at which temperature drops to less than 50°C delimits the depth of lesion formation. The use of higher power output to achieve higher tissue temperatures results in larger lesions by raising the temperature of the rim of resistively heated tissue to substantially more than 50°C for deeper tissue to reach the 50°C threshold required for tissue necrosis. However, the rim of heated tissue in direct contact with the ablating electrode conducts not only to deeper tissue but also to the electrode tip itself. Higher electrode temperatures either limit further energy delivery (in temperature-controlled power delivery mode) or increase electrode impedance as a result of coagulum formation; these effects potentially limit lesion size. Furthermore, tissue temperatures higher than 100°C are unsafe because they are associated with a higher risk of steam pops. Cooling of the ablating electrode (passively by using a

TABLE 7.1 Determinants of Radiofrequency Lesion Size

Electrode temperature	Lesion size increases with higher electrode temperature unless a coagulum is formed or power output is limited
RF power amplitude	Lesion size increases with higher RF power delivery given adequate tissue contact
Duration of RF application	Lesion size increases with increasing duration of RF application (up to 30–60 s for 4-mm tip standard RF, or up to 60–120 s for large or irrigated RF electrodes)
Electrode-tissue contact	Lesion size increases with improved tissue contact, unless RF power output is limited by increasing electrode temperatures and lack of electrode cooling
Electrode length	Lesion size increases with larger electrode length, unless RF power output is limited
Electrode orientation	With the same total power, perpendicular electrode orientation yields larger lesion volumes than parallel electrode orientation. When RF power level is unrestricted and is increased to maintain a constant current density, lesion size will increase proportionally to the electrode-tissue contact area, which is larger with parallel tip orientation
Electrode material	Gold electrodes have greater thermal conductivity than platinum, allowing for more RF power to be applied at constant temperature
Reference patch electrode size	Lesion size increases with increasing ground pad size and optimizing skin contact
Convective cooling	At any given power output (with no temperature restriction), RF lesion size decreases with increasing passive or active convective cooling
RF system polarity	At any given electrode temperature (with no power restriction), RF lesion size increases with increasing convective cooling
Electrode flexibility	Unipolar RF ablation produces narrower but deeper lesions. Bipolar RF ablation produces longer but shallower lesions
	Electrode flexibility improves tissue contact and can increase lesion size, unless RF power output is limited by increasing electrode temperatures and lack of electrode cooling

RF, Radiofrequency.

larger electrode length or actively by using catheter irrigation) can help diminish electrode heating, allowing for greater power delivery and creation of larger lesions. Several other factors can influence RF lesion size (Table 7.1).

Ablation Electrode Temperature

The relationship between lesion size and the recorded catheter tip temperature is complex and subject to several confounding factors. When electrode tip temperature closely resembles tissue temperature (the main determinant of lesion formation), lesion size appears to increase directly with electrode temperature up until the point of coagulum formation at the electrode-tissue interface, when further power delivery becomes limited. However, with good contact between catheter tip and tissue and low cooling of the catheter tip, the target temperature can be reached with little power, thus resulting in fairly small lesions although a high catheter tip temperature is being measured.

Furthermore, catheter tip temperature is not a reliable measure of tissue temperature, as it is also influenced by convective cooling, electrode-tissue contact, and type and location of the temperature sensor. A low catheter tip temperature can be caused by a high level of convective cooling, which allows a higher amount of RF power to be delivered to the tissue (because it is no longer limited by temperature rise of the ablation electrode) and yields relatively large lesions. This is best illustrated with active cooling of the ablation electrode using irrigation during RF energy delivery; the tip temperature is usually less than 40°C, which allows the application of high-power output for longer durations.

Radiofrequency Power Amplitude

Lesion size is proportional to the amount of RF power delivered *effectively* into the tissue. Higher RF power delivery increases the amount of directly heated tissue as well as tissue temperatures, resulting in greater depth of thermal injury and larger lesion size. However, the mere amplitude of RF power application does not necessarily translate to a larger amount of power delivered into the tissue, since RF power can be wasted into the surrounding blood pool due to poor electrode-tissue contact.

Duration of Radiofrequency Application

The RF lesion is predominantly generated within the first 10 seconds of target energy delivery and tissue temperatures, and it reaches a maximum after 30 seconds. Extension of RF application beyond 45 to 60 seconds during power-controlled RF delivery does not generally seem to increase lesion size further. However, lesions created using large or irrigated RF electrodes have a longer half time of lesion growth, and extended ablation (60 to 120 seconds) can potentially help create larger lesions.

Electrode-Tissue Contact

Catheter electrode-tissue contact pressure is a major determinant of lesion size. Data indicate that increasing the firmness of contact (contact force) is comparable to increasing RF power; that is, the same tissue temperatures and lesion size can be reached at a much lower power level when tissue contact is optimized.^{14,15}

The efficiency of energy transfer to the myocardium (i.e., temperature rise per watt of applied power) largely depends on the electrode-tissue contact. Increasing contact force can improve the efficiency of RF lesion formation by several mechanisms: (1) expanding the area of the contact footprint of the electrode on myocardial tissue by embedding it deeper within the soft myocardium, which leads to a higher amount of RF power that can be effectively delivered to the tissue; (2) reducing the electrode surface exposed to surrounding blood pool and, hence, reducing RF current shunting into the low-impedance blood pool; (3) improving stability of the electrode-tissue contact and reducing catheter sliding with cardiac motion, which improves the efficiency of lesion formation; and (4) stretching of the myocardium, bringing the epicardium closer to the ablation electrode and, hence, improving transmural of the RF lesion.¹⁶

However, at a certain moderate contact force, further increase in contact firmness results in progressively smaller lesions because a lesser amount of RF power is required to reach target temperature. The temperature rise of the ablation electrode signals excessive tissue heating and limits power delivery in a temperature-controlled system. Reduced convective cooling of the ablation electrode (because of lesser interface

with the blood pool) results in higher electrode temperatures and can further reduce RF current delivery.

Electrode Length

Ablation catheters have tip electrodes that are conventionally 4 mm long and are available in sizes up to 10 mm long (see eFig. 4.3). An increased electrode size reduces the interface impedance with blood and tissue, but the impedance through the rest of the patient remains the same. Hence, the ratio between interface impedance and the impedance through the rest of the patient is lower with an 8-mm electrode than with a 4-mm electrode, which reduces the efficiency of power transfer to the tissue. Therefore with the same total power, lesions created with a larger electrode are always smaller than lesions created with a smaller electrode (Fig. 7.6). A larger electrode size also creates a greater variability in power transfer to the tissue because of greater variability of tissue contact, and tissue contact becomes much more dependent on catheter orientation with longer electrodes. Consequently, an 8-mm electrode may require a 1.5 to 4 times higher power level than a 4-mm electrode to create the same lesion size.

On the other hand, when the power is not limited, catheters with large distal electrodes create larger lesions, both by increasing the ablation electrode surface area in contact with the bloodstream (resulting in an augmented convective cooling effect) and by increasing the volume of tissue directly heated because of an increased surface area at the electrode-tissue interface (see Fig. 7.6). However, this assumes that the electrode-tissue contact, tissue heat dissipation, and blood flow are uniform throughout the electrode-tissue interface. As the electrode size increases, the likelihood that these assumptions are true diminishes because of variability in cardiac chamber trabeculations and curvature, tissue perfusion, and intracardiac blood flow, which affect the heat dissipation and tissue contact. These factors result in unpredictable lesion size and uniformity for electrodes more than 8 mm long.

There is a potential safety concern with the use of long ablation electrodes because of nonuniform heating, with maximal heating occurring at the electrode edges. Thus, large electrode-tipped catheters with

only a single thermistor can underestimate maximal temperature and allow char formation and potential thromboembolic complications. Catheter tips with multiple temperature sensors at the electrode edges are preferable for temperature feedback. In addition, the greater variation in power delivered to the tissue and the greater discrepancy between electrode and tissue temperature make it difficult to avoid steam pops and char formation. Another point of concern is that the formation of char may only minimally affect electrode impedance by covering a much smaller part of the electrode surface. Therefore the lower electrode temperature and the absence of any impedance rise may erroneously suggest a safer ablation process.

The principal limitations of a large ablation electrode (8 to 10 mm in length) are the reduction in mobility and the flexibility of the catheter (which can impair positioning of the ablation electrode) and a reduction in the resolution of recordings from the ablation electrode, thus making it more difficult to identify the optimal ablation site. A larger electrode dampens the local electrogram, especially that of the distal electrode. With an 8- or 10-mm long distal and a 1-mm short proximal ring electrode, the proximal electrode can be the main source for the bipolar electrogram; this then confuses localization of the optimal ablation site. In contrast, a smaller electrode improves mapping accuracy and feedback of tissue heating; its only drawback is the limited power level that can be applied to the tissue.

Electrode Orientation

The effect of catheter orientation on lesion size depends on the presence of passive or active cooling, whether or not power delivery is restricted, the length of the ablation electrode, as well as the placement of the temperature sensors relative to the portion of the electrode in contact with tissue. Lesion size is only slightly affected by catheter tip orientation using 4- or 5-mm-long tip catheters; the effects of catheter orientation become more pronounced for larger ablation electrodes.

When the catheter tip is perpendicular to the tissue surface, a much smaller surface area is in contact with the tissue (resulting in increased current density at the electrode-tissue interface) and larger area exposed to the circulating blood pool (resulting in augmented convective cooling) than when the catheter electrode tip is lying on its side. On the other hand, parallel tip orientation provides larger electrode-tissue contact area (resulting in less power waste into the blood stream and less current density at the electrode-tissue interface). Therefore with the same total power, perpendicular electrode orientation yields larger lesion volumes than parallel electrode orientation. However, if the RF power level is unrestricted and is increased to maintain a constant current density, lesion size will increase proportionally to the electrode-tissue contact area, which is larger with parallel tip orientation.

Furthermore, the character of the lesion created with temperature control depends on the placement of the temperature sensors relative to the portion of the electrode in contact with tissue. Thus, the orientation of the electrode and its temperature sensors determines the appropriate target temperature required to create maximal lesions while avoiding coagulum formation caused by overheating at any location within the electrode-tissue interface.

Electrode Material

Although platinum-iridium electrodes have been the standard for most RF ablation catheters, gold exhibits excellent electrical conductive properties, as well as a more than four times greater thermal conductivity than platinum (300 vs. 70 W/m K), although both materials have similar heat capacities (130 and 135 J/kg K). The higher thermal conductivity of gold can potentially lead to a higher mean rate of power delivery because of better heat conduction at the tissue-electrode interface and to enhanced cooling as a result of heat loss to the surrounding blood

Fig. 7.6 Effect of Electrode Size and Power Delivery on Lesion Size. Representative blocks of myocardium are shown with lesions (dark shading) resulting from optimal radiofrequency energy delivery for each electrode type. The effect of 20 W delivered for 30 seconds is shown for a 4-mm electrode (left) and an 8-mm electrode (center). The larger electrode dissipates more of the energy into the blood pool and thus paradoxically creates a smaller lesion. Because of electrode cooling from its larger surface area, the same 8-mm electrode can deliver more power than the 4-mm electrode and could create a larger lesion (right).

with this electrode material. Therefore gold electrodes allow for greater power delivery to create deeper lesions at a given electrode temperature without impedance increases. Enhanced electrode cooling allows for more RF power to be applied at constant temperature, before the temperature limit is reached or before the impedance of the electrode rises. However, the higher thermal conductivity of gold electrodes is no longer an advantage in areas of low blood flow (e.g., between myocardial trabeculae), where convective cooling at the electrode tip is minimal. Under these circumstances, electrode materials with a low thermal conductivity can produce larger lesions.¹⁷

Conflicting results were observed in clinical studies comparing 8-mm gold-tip with platinum-iridium-tip catheters for ablation of the cavotricuspid isthmus (CTI). During catheter ablation of the slow AVN pathway in patients with atrioventricular nodal reentry tachycardia (AVNRT), no significant differences were observed between 4-mm gold-tip and platinum-iridium-tip catheters in the primary endpoint or in the increases of power or temperature at any of the measured time points. However, ablation with gold electrodes seemed to be safe and well tolerated and specifically did not increase the risk of AV block. Interestingly, a significant reduction of charring on gold tips was observed, compared with platinum-iridium material, a finding suggesting a possible advantage of this material beyond its better conduction properties.

An irrigated gold-tip ablation catheter was recently tested and found to allow for improved energy delivery at lower catheter-tip temperatures and at lower irrigation flow rate compared to irrigated platinum-iridium-tip catheters.^{17,18}

Reference Patch Electrode Location and Size

The RF current path and skin reference electrode interface present significant impedance for the ablation current flow, thereby dissipating part of the power. Increasing patch size (or using two patches) and optimizing skin contact reduce electrical impedance at skin-patch interface (and minimize power dissipation) and provide for increased heating at the electrode-endocardium interface and thus increase ablation efficiency and increase lesion size. On the other hand, the position of the dispersive electrode (on the patient's back or thigh) has little effect on the size of the resulting lesion.

Convective Cooling

The ablation electrode temperature is dependent on the opposing effects of heating from the tissue and cooling by the blood flowing around the electrode. Because ablation lesion size is primarily dependent on the RF power delivered to the tissue, lesion size varies with the magnitude of convective cooling of the ablation electrode. Electrode cooling can be achieved passively (by local blood flow) or actively (by electrode irrigation).

At any given electrode temperature, the RF power delivered to the tissue is significantly reduced in areas of low local blood flow (e.g., deep pouch in the CTI, dilated and poorly contracting atria, between myocardial trabeculae). The reduced cooling associated with low blood flow causes the electrode to reach the target temperature at lower power levels, and if the ablation lesion is temperature-controlled, power delivery will be limited. In these locations, increasing electrode temperature to 65°C or 70°C only minimally increases RF power but it does increase the risk of thrombus formation and impedance rise. Conversely, increasing local blood flow is associated with increased convective cooling of the ablation electrode. Passive electrode cooling can be promoted by using large electrode length or electrode material with high thermal conductivity. Convective cooling can also be achieved by internal or external saline irrigation of the ablation electrode.

With enhanced convective cooling, more power is delivered to the tissue to reach and maintain target temperature, thus resulting in larger

lesion volumes. However, when RF power output is limited, increased convective cooling curtails tissue heating due to increased heat loss into the blood pool. Therefore at any given power output (with no temperature restriction), RF lesion size decreases with increasing convective cooling. Conversely, at any given electrode temperature (with no power restriction), RF lesion size increases with increasing convective cooling.

Radiofrequency System Polarity

Most RF lesions are created by applying energy in a unipolar fashion between an ablating electrode touching the myocardium and a grounded reference patch electrode placed externally on the skin. Bipolar energy delivery produces larger lesions than unipolar delivery. In general, the unipolar configuration creates a highly localized lesion, with the least amount of surface injury (i.e., narrower but deeper lesions), while bipolar RF ablation produces longer but shallower lesions.

Electrode Flexibility

An irrigated catheter with a flexible tip design (Cool Flex, St. Jude Medical) allows the ablation tip to flex and provide more uniform distribution of force and a larger, more stable tissue-contact (nonperpendicular orientations) in beating hearts, regardless of catheter orientation relative to targeted tissue (eFig. 7.3). This design also enhances cooling of the catheter-tissue interface through open irrigation with numerous slits that are uniformly spread throughout the electrode for radial cooling, which also creates preferential flow toward the tissue when the catheter tip is flexed, as in a drag lesion. Four additional ports are built into the distal tip for cooling of the target tissue when the catheter is in a perpendicular orientation.¹⁹

In one report, the Cool Flex flexible-tip catheter was associated with larger ablation lesions at similar depths compared to the rigid-tip catheter. This was mainly related to enhanced cooling of the catheter tip-tissue interface which allowed more power delivery to targeted tissue, especially in nonperpendicular catheter orientation which would also result in a larger contact area during RF applications with the flexible tip. The performance of the rigid-tip catheter seemed to be significantly affected by catheter orientation which was not the case with the flexible-tip catheter.¹⁹

Monitoring Radiofrequency Lesion Formation

The goal of optimizing RF ablation is to create an adequate-sized lesion while minimizing the chance of coagulum formation at the electrode itself and steam formation within the tissue. As discussed previously, for ablation to be effective, RF power must be increased sufficiently to achieve temperatures substantially higher than 50°C at the tissue directly in contact with the ablating electrode in order to achieve tissue necrosis. At the same time, for ablation to be safe, the highest tissue temperature must be maintained at less than 100°C to prevent steam pops and coagulum formation. Monitoring of RF energy delivery is therefore very important to help achieve successful as well as safe ablation.

RF lesion creation is influenced by many factors, some of which can be controlled, whereas others are variable and can be unpredictable. With standard RF ablation, power delivery is titrated to electrode temperature, typically at 55°C to 65°C. Higher temperatures can increase the chance of reaching 100°C at edges of the ablation electrode (away from the temperature sensor), thus resulting in coagulum formation. An increase in tissue temperature is accompanied by a decrease in impedance, also a reliable marker of tissue heating. Impedance reduction and temperature rise correlate with both lesion width and depth; maximum temperature rise is best correlated with lesion width, and maximum impedance reduction is best correlated with lesion depth.

The efficiency of tissue heating (i.e., the temperature per watt of applied power) is dependent on several variables, including catheter

eFig. 7.3 Ablation Catheter With a Flexible Tip Design. Cool Flex irrigated-tip ablation catheter. (Courtesy St. Jude Medical, Minneapolis, MN, United States.)

stability, electrode-tissue contact pressure, electrode orientation relative to the endocardium, effective electrode contact area, convective heat loss into the blood pool, and target location. Thus, applied energy, power, and current are poor indicators of the extent of lesion formation, and the actual electrode-tissue interface temperature remains the only predictor of the actual lesion size. Currently, although less than ideal, monitoring temperature and impedance are used to help ensure adequate but not excessive heating at the electrode-tissue interface. Newer technologies may be implemented in the future to monitor tissue temperatures during RF delivery, including infrared sensors and ultrasound transducers.

Impedance Monitoring

The magnitude of the current delivered by the RF generator used in ablation is largely determined by the impedance between the ablation catheter and the dispersive electrode. This impedance is influenced by several factors, including intrinsic tissue properties, catheter contact pressure, catheter electrode size, dispersive electrode size, presence of coagulum, and body surface area. Impedance measurement does not require any specific catheter-based sensor circuitry and can be performed with any catheter designed for RF ablation.²⁰

As tissue temperature rises during RF energy application, ions within the tissue being heated become more mobile, resulting in a decrease in impedance to current flow. Hence a drop in impedance resulting from RF ablation can serve as a real-time marker of tissue heating. Although the impedance drop during RF ablation occurs mainly because of a reversible phenomenon, rather than from an irreversible myocardial tissue damage secondary to ablation, lesion diameter and depth have been shown to correlate well with impedance decrease, with an even more direct relationship than measured temperature.²¹

Typically, the impedance associated with firm catheter contact (before tissue heating has occurred) is 90 to 120 Ω . When catheter contact is poor, the initial impedance is 20% to 50% less, because of the lower resistivity of blood. Moreover, larger electrodes have larger contact area and consequently lower impedance. A 5- to 10- Ω reduction in impedance is usually observed in clinically successful RF applications, it correlates with a tissue temperature of 55°C to 60°C, and it is rarely associated with coagulum formation. Larger decrements in impedance reflect excessive tissue heating and are noted when coagulum formation is imminent. Once a coagulum is formed, an abrupt rise in impedance to more than 250 Ω is usually observed.²⁰

To titrate RF energy using impedance monitoring alone, the initial power output is set at 20 to 30 W and is then gradually increased to target a 5- to 10- Ω decrement in impedance. When target impedance is reached, power output should be manually adjusted throughout the RF application to maintain the impedance in the target range. A larger decrement of impedance should prompt reduction in power output. Lack of impedance drop during RF energy application can reflect inefficient energy delivery to the tissue due to poor catheter-tissue or catheter instability, and should prompt catheter repositioning and verification of adequate tissue contact.

The drop in impedance as a monitoring tool has several limitations. When blood flow rates are low, blood can also be heated, and electrode impedance drops accordingly. Moreover, a large rise in tissue temperature at a small contact area and a smaller rise with better tissue contact can result in a similar drop in impedance. Inversely, similar tissue heating with different tissue contact can result in a different change in impedance. In addition, resistive heating nearby is fast, whereas conductive heating to deeper layers is relatively slow. The former, at close distance, has a much greater effect on impedance than the latter, which occurs at greater distance. Therefore the drop in impedance during RF

application is not a reliable parameter for estimating deep tissue heating and lesion growth.

Although coagulum formation is usually accompanied by an abrupt rise in impedance, the absence of impedance rise during ablation does not guarantee the absence of coagulum formation on the tissue contact site, which can unnoticeably be created on the tissue surface rather than on the ablation electrode. In addition, with large ablation electrodes, formation of blood clots may only minimally affect electrode impedance by covering a much smaller part of the electrode surface. Any increase in impedance during RF application can, however, indicate the beginning of coagulum formation or unintended catheter movement; in either case, RF application is discontinued.

Electrode Temperature Monitoring

Temperature monitoring utilizes dedicated sensors within the catheter tip. Two types of sensors are available: thermistor and thermocouple. No catheter or thermometry technology has been demonstrated to be superior in clinical use. Conventional electrode catheters with temperature monitoring report the temperature only from the center of the electrode mass with one design or from the apex of the tip of the catheter with another design, and it is likely that the measured temperature underestimates the peak tissue temperature. Therefore it is best if target temperatures no higher than 70°C are selected in the clinical setting.

Monitoring of catheter tip temperature and closed-loop control of power output are useful to accomplish effective heating at the target area while avoiding excessive heating at the tissue surface that can lead to coagulum formation. However, catheter tip temperature is influenced by cooling effects and electrode-tissue contact and, thus, correlates poorly with lesion size. Tissue temperature can be markedly higher than catheter tip temperature; a higher target temperature can increase the incidence of tissue overheating associated with coagulum formation and steam pops. High-flow areas are associated with more efficient cooling of the ablation electrode; hence, more RF power is delivered to the tissue to reach target temperature, thus resulting in relatively large lesions and vice versa.

The discrepancy between monitored electrode temperature and tissue temperature is significantly exaggerated by active cooling of the ablation electrode. The thermal effects on the electrode temperature are dependent on electrode heating from the tissue, internal cooling by the irrigation fluid, and external cooling from blood flow or open irrigation. With high irrigation flow rates, catheter tip temperature is no longer representative of tissue temperature, and therefore feedback cannot be used to guide power output. The difference between the electrode temperature and tissue-electrode interface temperature is greater with the closed-loop electrode than with the open-irrigation electrode. The discrepancy is likely to be increased in areas of high blood flow, by increasing the irrigation flow rate, or by cooling the irrigant. Saline-irrigated catheters result in peak tissue heating several millimeters from the electrode-tissue interface. Because maximum tissue heating does not occur at the electrode-tissue interface, the value of temperature and impedance monitoring is limited with this type of catheter.

Therefore monitoring lesion formation and optimizing power delivery during cooled RF ablation remain challenging. Appropriate energy titration is important to allow greater power application and to produce large lesions while avoiding overheating of tissue with steam formation leading to pops. Moreover, the inability to assess tissue heating, and hence to titrate power to an objective endpoint, prevents the operator from determining whether unsuccessful applications are caused by inadequate mapping or inadequate heating. In general, temperatures exceeding 42°C to 45°C with power greater than 30 W during open-irrigation RF ablation can be associated with a greater risk of steam

pops and impedance rises, particularly during long RF applications, exceeding 60 seconds. Steam pops are often, but not always, audible. A sudden decrease in temperature, sudden catheter movement (as a consequence of the pop blowing the catheter out of position), and a sudden change in impedance are all potential indications that a pop has occurred.

Electrophysiological Effects of Ablation

In addition to impedance and catheter tip temperature monitoring, effects of tissue heating on recorded electrograms or the arrhythmia are important indicators for monitoring lesion formation. Interruption of tachycardia (VT, atrial flutter [AFL], supraventricular tachycardia) or block in conduction over a pathway (AVN or BT) during the process of ablation provide immediate feedback about the disruption of tissue integrity. In addition, an increase in pacing threshold and a decrease in electrogram amplitude can indicate tissue damage. These factors, however, are not easily monitored during the RF application, particularly the change in pacing threshold. Moreover, the decrease in electrogram amplitude is often not visible during RF application because of superimposed electrical artifact.²²

Of note, reductions in amplitude and steepness of the local electrogram as indicators of tissue heating apply only to the unipolar distal electrogram. With a bipolar recording, the signal from the ring electrode may dominate the electrogram, and the bipolar amplitude can theoretically even rise during ablation because of a greater difference between the signals from both electrodes.

Tissue Temperature Monitoring

Technologies to directly measure tissue temperature during RF ablation (which is the primary determinant of lesion formation) are currently not available for clinical use. Novel technologies are being evaluated, including microwave radiometry, near-field ultrasound thermal strain imaging, and magnetic resonance thermometry.

Direct monitoring of tissue temperature enables titration of RF power output, duration of energy application, and active cooling to optimize lesion formation. Maintaining temperatures during ablation in a “safe and effective” zone (50°C to 80°C) helps achieve adequate RF lesion and prevent steam pops.¹³

Titration of Standard Radiofrequency Energy

Monitoring catheter tip temperature and closed-loop control of power output are useful to accomplish effective heating at the target area while avoiding excessive heating at the tissue surface that can lead to coagulum formation. However, catheter tip temperature is influenced by cooling effects and electrode-tissue contact and, thus, correlates poorly with lesion size.

Titration of RF energy using temperature monitoring is usually done automatically by a closed-loop temperature monitoring system. When manual power titration is directed by temperature monitoring, the power initially is set to 20 to 30 W and then is gradually increased until the target temperature is achieved. With both manual and automatic power titration, a change in power output is frequently required throughout the RF application to maintain the target temperature. Application of RF energy is continued if the desired clinical effect is observed within 5 to 10 seconds after the target temperature or impedance is achieved. If the desired endpoint does not occur within this time, the failed application is probably because of inadequate mapping. If the target temperature or impedance is not achieved with maximum generator output within 20 seconds (the time it takes to achieve sub-endocardial steady-state temperature), the RF application can be terminated, and catheter adjustment should be considered to obtain better tissue contact.

The target ablation electrode temperature varies according to the arrhythmia substrate. For AVNRT, target temperature is usually 50°C to 55°C. For BT, AV junction, AT, and VT, higher temperatures (55°C to 60°C) are usually targeted.

When using 4-mm-tip catheters, the target temperature should be lower than 80°C. In high-flow areas in the heart, the disparity between tip temperature and tissue temperature is large and a lower cutoff temperature (e.g., 60°C) should be considered. Conversely, in low flow areas tissue temperature is much better reflected by tip temperature and a higher target temperature can be considered (e.g., 70°C to 80°C). The duration of RF application is usually limited to 30 to 60 seconds for nonirrigated 4-mm-tip electrodes. The lesion is predominantly formed within the first 30 seconds. A longer duration does not create larger lesions.

When using 8-mm-tip catheters, a larger portion of the ablation electrode is exposed to the blood and thus cooled by blood flow, and a relatively large difference between catheter tip temperature and tissue temperature can be expected. Consequently, a moderate target temperature (e.g., 60°C) should be chosen; the RF power may be limited to 50 to 60 W to avoid tissue overheating and coagulum formation.

It is important to recognize that prevention of coagulum formation is difficult, even with temperature and impedance monitoring. The clot first adheres to the tissue because that is the site with the highest temperature and may only loosely attach to the cooler electrode. The denatured proteins probably have higher electrical impedance than blood, but the contact area with the electrode can be small, and RF impedance may not rise noticeably. The absence of flow inside the coagulum and its presumed higher impedance accelerate local heating and, because of some contact with the electrode, also accelerate heating of the electrode. Desiccation and adherence to the electrode then lead to coagulum formation on the metal electrode and impedance rise. Automatic power reduction by temperature-controlled RF ablation compensates for the reduction of electrode cooling and may prevent desiccation and impedance rise. The coagulum, however, can still be formed as demonstrated by experimental *in vivo* studies, and this can remain unnoticeable until it detaches from the tissue. Therefore the absence of thermal and electrical phenomena does not imply that the ablation has been performed safely.

Titration of Cooled Radiofrequency Energy

Active cooling of the ablation electrodes makes lesion formation more difficult to monitor and control. As noted, the discrepancy between monitored electrode temperature and tissue temperature is significantly exaggerated by active electrode cooling; as a result, electrode temperature is no longer a reliable predictor of lesion formation. Several other indicators of tissue heating can be monitored, including impedance and EP effects of ablation. Adjustment of RF power output, duration of RF application, and irrigant flow rate help modulate lesion formation.

The most easily controllable factors are the power output and duration of RF application. Although the optimal method for adjusting power during saline-irrigated RF ablation is not yet clearly defined, some useful guidelines have emerged. The most commonly recommended approach is to perform ablation in a power-controlled mode, typically starting at 20 to 30 W and gradually increasing power to achieve evidence of tissue heating or damage. An impedance fall likely indicates tissue heating, similar to that observed with conventional RF ablation. When catheter temperature is between 28°C and 31°C, power can be ramped up, watching for a 5- to 10- Ω impedance fall. Measured electrode temperature will generally increase, and electrode temperatures of 37°C to 40°C are commonly achieved. Power levels typically used during open-irrigation ablation depend on the site of ablation: 25 to

30 W in the left and right atrial free wall, 35 to 40 W for CTI and mitral isthmus ablation, 50 W in the LV, and 20 W in the coronary sinus (CS).

Also, instead of increasing the power (which increases the likelihood of steam pops) to achieve the desired EP effect, the duration of energy application may be increased. A moderate power of 20 to 35 W with a relatively long RF duration of 60 to 300 seconds may be considered to achieve relatively large lesions, with a limited risk of crater formation.

The flow rate of the irrigant determines the degree of cooling. Faster flow rates likely allow greater power application without impedance rises, increase the difference between tissue and electrode temperature, and thereby potentially increase the risk of steam pops if temperature is used to guide ablation. With the internally irrigated ablation system, the approved flow rate is fixed at 36 mL/min and is not currently manipulated. With the externally irrigated ablation system, an irrigation flow rate of 10 to 17 mL/min during RF application (and 2 mL/min during all other times to maintain patency of the pores in the electrode) may be selected in a power-controlled mode with a delivered power of up to 30 W. The irrigation flow rate should be increased to 20 to 30 mL/min with delivery of more than 30 W, to avoid excessive heating of the superficial tissue layers. Using a lower irrigation flow rate (10 mL/min) in the left atrium (LA) can help maintain some temperature feedback, with a cutoff temperature of 43°C. The temperature is usually set at 40°C to 45°C. If the temperature at the tip is lower than 40°C, the flow rate may be reduced. If the desired power is not met because the target temperature is reached at a lower power, the irrigation flow rate may be increased to a maximum of 60 mL/min. Parameters for epicardial ablation are similar to those used for endocardial ablation. New catheter designs employing lower irrigation flow rates (e.g., ThermoCool SF, Biosense Webster), in order to maintain adequate electrode cooling but with less total fluid load during long procedures, are also available.

In addition, the temperature of the irrigant can be manipulated. Cooling the irrigant can potentially allow power delivery to be increased without coagulum formation. However, the cooled irrigant is warmed as it passes through the tubing to reach the catheter and through the length of the catheter, and the impact of cooling the irrigant has not been well studied. In most studies, the irrigant that enters the catheter is at room temperature.

Temperatures exceeding 42°C to 45°C with power greater than 30 W during open-irrigation RF ablation can be associated with a greater risk of steam pops and impedance rises, particularly during long RF applications, exceeding 60 seconds. Steam pops are often, but not always, audible. A sudden decrease in temperature, a sudden catheter movement (as a consequence of the pop blowing the catheter out of position), and a sudden change in impedance are all potential indications that a pop has occurred. Whether the catheter is maintained in a stable position, as opposed to dragging it across the tissue during linear ablation, also likely influences tissue heating. High power can be applied continuously during dragging with little risk of excessive heating, although the duration of time to spend at each site to create an effective lesion may be difficult to ascertain. As a rule, the lowest effective power setting, shortest duration, and fewest applications should be employed whenever possible.

During open-irrigation RF ablation, initiation of irrigation results in a drop of electrode temperature by several degrees. Failure of electrode temperature to decrease indicates a lack of irrigant flow. When power delivery begins, catheter tip temperature should rise to 36°C to 42°C (the presence of rising temperature, not the magnitude, reflects tissue heating). Temperatures higher than 40°C achieved with low power (less than 20 W) can indicate that the electrode is in a location with

little or no cooling from the surrounding circulating blood, or that there is a failure of the catheter cooling system that requires attention. In contrast, the absence of any increase in tip temperature should raise the possibility of poor catheter contact.

With the internally irrigated system, the room temperature irrigant flowing at 36 mL/min typically cools the measured electrode temperature to 28°C to 30°C. During RF application, the electrode temperature increases; temperatures of 50°C can indicate that cooling is inadequate or has stopped, which warrants termination of RF application. The measured impedance typically decreases during cooled RF ablation by 5 to 10 Ω , in a manner similar to that observed during standard RF ablation.

Optimizing Catheter-Tissue Contact

Optimizing catheter-tissue contact and minimizing catheter motion are critical for achieving safe and effective lesion formation. Poor or unstable contact leads to ineffective tissue heating and lesion formation as well as potential collateral injury to adjacent structures. Suboptimal contact can also result in partially successful ablation lesions, which can transiently interrupt the arrhythmia or eliminate its inducibility but without permanent destruction of the arrhythmogenic substrate. This outcome hinders further mapping and ablation efforts and predicts higher risk of arrhythmia recurrence. In addition, repetitive RF applications with inconsistent contact can result in tissue edema that can prevent effective lesion formation during later RF energy applications (even with optimized tissue contact). Therefore stable catheter contact should be ensured before each and every ablation lesion.²³

On the other hand, excess catheter pressure against the cardiac wall during RF ablation can cause tissue compression and thinning and, as a result, increase the risk of steam pop and cardiac perforation. Excessive contact force can also result in stretching and potential disruption of the chamber wall, even without RF ablation. Tenting of the chamber wall can potentially bring the tip of the ablation catheter in closer proximity to adjacent extracardiac structures (e.g., esophagus, phrenic nerve), increasing the risk of collateral damage during RF ablation.¹⁶

Several methods to both optimize catheter contact and minimize catheter motion have been developed. General anesthesia and high-frequency jet ventilation have been used to optimize catheter stability and minimize the degree of respiratory effects on catheter contact during AF ablation. In addition, the use of steerable sheaths facilitates achieving stable and firm tissue contact, at least partly by increasing the column rigidity of the catheter-sheath combination. Furthermore, several approaches have been employed to ensure adequate catheter-tissue contact during RF ablation (Table 7.2). Most of those approaches utilize indirect measures that represent imperfect surrogate of catheter-tissue contact. In addition, while those methods can potentially suggest inadequate tissue contact, they are far less reliable in estimating the force applied by the catheter tip on the chamber wall. More recently, real-time measurement of tissue contact and contact force has become available in several irrigated ablation catheters, and can potentially improve RF ablation efficacy and safety.¹⁶

Record Electrograms

Local electrogram characteristics (sharp, near-field electrogram vs. far-field electrogram), beat-to-beat stability of recorded electrograms, and pacing capture threshold provide some information about tissue contact. However, electrograms only provide transient contact information and have been shown to be imprecise in judging contact. Also, assessing contact with abnormal myocardial tissue (e.g., infarct scar) can be difficult, since local electrograms are frequently low amplitude and local capture may not be achievable.^{16,20,23}

TABLE 7.2 Strategies to Optimize Electrode-Tissue Contact and Stability

Recorded electrograms	Local electrogram demonstrating sharp, near-field signals with beat-to-beat stability and low pacing capture threshold
Fluoroscopy	Catheter shaft and tip move congruent to chamber wall movement
Tactile feedback	Tactile sensation by operator can provide some feedback regarding catheter contact to chamber wall, resistance of catheter advancement, as well as movement with cardiac wall
Intracardiac echocardiography	Visualization of the catheter tip in contact with tissue
Temperature monitoring	Increased electrode-tissue contact results in higher tissue temperatures, and the plateau is achieved later
Impedance monitoring	Firm tissue contact is modestly correlated with increased initial impedance levels and a larger initial drop of impedance during RF application
Contact force monitoring	Maintaining adequate contact can be guided by contact force sensors
Electrogram-gated pulsed RF delivery	Gating pulsed RF power delivery to recorded electrogram can potentially compensate for cardiac motion
Steerable sheaths	Using steerable sheaths facilitates achieving stable and firm tissue contact

RF, Radiofrequency.

Fluoroscopy

Fluoroscopy can be useful to assess contact by monitoring catheter shaft and tip movement relative to the heart. However, utilization of fluoroscopy for this purpose significantly increases radiation exposure to both the patient and operator. In addition, fluoroscopic monitoring is difficult to titrate and is not helpful for avoiding the application of excess catheter pressure against the cardiac wall.²³

Tactile Feedback

Tactile feedback is often used as an indirect surrogate to catheter contact to the chamber wall. Tactile feedback, however, is subjective, a function of the operator's experience, and is difficult to titrate. The use of steerable introducer sheaths can help improve catheter stability and contact, but such a technique often dampens the tactile feedback.²⁰

Data suggest that relying on tactile feedback alone is not sufficient, and stronger effort should be made to gather as much information as possible about contact from as many different sensing modalities as possible. Furthermore, the use of three-dimensional (3-D) mapping systems alone, without the aid of fluoroscopy, to supplement tactile feedback may not be adequate.²⁴

Intracardiac Echocardiography

Visualization of the catheter tip with ICE can help confirm tissue contact. However, catheter visualization with ICE at all endocardial locations and throughout the cardiac cycle usually is not feasible.

Temperature Monitoring

During RF energy delivery, increased electrode-tissue contact results in higher tissue temperatures, and the plateau is achieved later. Thus, failure of electrode temperature to increase despite high RF energy output suggests poor tissue contact. Nevertheless, several factors can cause discrepancies between the real tissue temperature and the catheter tip temperature, including catheter tip orientation, cooling effect of blood flow, and electrode irrigation.

Impedance Monitoring

Baseline electrode impedance and changes in electrode temperature and impedance during RF application provide information regarding the degree of electrode-tissue contact. Higher baseline impedance with greater contact is thought to be due to increasing the electrode-tissue interface area and reducing the interface area between the electrode and the low-resistivity blood pool. In animal studies, firm tissue contact was associated with increased baseline impedance levels (by a mean of 22%), and a larger initial drop of impedance (within the first 20 seconds of RF application).^{20,14} However, clinical studies using real-time contact force measurements showed that impedance measurements (both

baseline levels and subsequent impedance fall) have poor to modest efficacy as surrogate markers for catheter-tissue contact force and, hence, may not be useful in predicting catheter-tissue contact force in humans.^{25,26}

Electroanatomical Catheter Localization

Modern electroanatomic mapping systems enable the creation of a virtual anatomical intracardiac geometry by moving the catheter in all directions throughout the cardiac chamber of interest. Points at outermost boundaries are used to depict the outer geometry (shell), while points inside to the outer shell are automatically removed. Also, pre-acquired cardiac magnetic resonance or computed tomography (CT) images and intraprocedural ICE images can be registered on the real-time 3-D electroanatomic maps. Those systems also estimate the proximity of the ablation electrode to the virtual shell.

However, anatomical distortion and expansion of the virtual image are common due to the inconsistent contact force on the catheter tip during the process geometry creation. Therefore the 3-D anatomical geometries generated by different mapping methods are not reliable to establish catheter tip-tissue contact. Of note, studies evaluating the fidelity of those technologies in AF ablation procedures have showed that the 3-D ICE-derived LA geometric reconstruction is smaller than reconstructions derived from electroanatomic virtual shell and merged 3-D ICE or CT images.^{27–29}

Contact Force Monitoring

Two different designs of open-irrigation ablation catheters have been developed to measure real-time catheter-tissue contact force during catheter mapping and ablation (Fig. 7.7). The first design (ThermoCool SmartTouch CF, Biosense Webster, Diamond Bar, CA, United States) uses a small spring connecting the ablation tip electrode to the catheter shaft, with a magnetic transmitter and location sensors to measure microdeflections of the spring. The second design (TactiCath, Endosense, St. Jude Medical, St. Paul, MN, United States) incorporates a force sensor between the second and third electrode, consisting of a deformable body and three optical fibers to measure microdeformations that correlate with the force applied to the catheter tip.^{14,30–33}

Contact force ablation catheters show promise for improving the outcome of complex catheter ablation procedures. Contact force sensing may also improve the safety of catheter ablation by avoiding excessive contact force and, hence, decreasing the risk of perforation or steam pops. Contact force catheters may also enhance operators' catheter manipulation skills by providing real-time feedback of catheter-tissue contact.¹⁴

Nevertheless, the range of contact forces that are both effective and safe is yet to be determined. Clinical studies suggested that at least 10 g

Fig. 7.7 Comparison of Fiberoptic and Spring-Based Contact Force Sensors for Radiofrequency Ablation. Two different technologies are currently used to measure contact force. One catheter uses a sensor based on a Fabry-Pérot interferometer (*left*). Force on the distal catheter tip changes the length of an air cavity, altering the reflection pattern of light shining through two adjacent semireflective mirrors. This changes the interference pattern of the light, and this pattern is transmitted back to the operating system to calculate the contact force. A second catheter uses a spring-based sensor (*right*). Force on the distal tip of the catheter compresses a precision spring. Deflection (x) of the spring is determined by measuring micromovements of a transmitter coil distal to the spring, and the contact force is calculated using the known spring characteristics (k). (From Barnett AS, Bahnson TD, Piccini JP. Recent advances in lesion formation for catheter ablation of atrial fibrillation. *Circ Arrhythm Electrophysiol*. 2016;9:e003299.)

of contact force is required to optimize lesion formation. The average contact force used in these studies was greater than 10 g (range 10 to 40 g). Above 10 g, there is a wide margin of safety.^{31,34,35} Experimental studies showed that, at constant RF power and application time, increasing contact force (2 to 40 g) significantly increased tissue temperature (at depths of 3 to 7 mm) with significant increases in RF lesion depth, diameter, and volume. Lesion size was more dependent on contact force than on power. However, higher contact force is associated with increases in the frequency of steam pop and coagulum formation.¹⁴ On the other hand, in another study, low-force ablation (less than 10 g) resulted in RF ablation lesion size, quality, and transmuralty equivalent to those of high-force ablation (greater than 20 g) in an atrial ablation model. During temperature-controlled RF energy delivery, higher RF power output appeared to compensate for reduced catheter-myocardium energy transfer at low contact force.^{34,36,37}

More recently, a novel automated ablation lesion tagging technology based on catheter stability information (CARTO 3, VisiTag Module, Biosense Webster, Diamond Bar, CA, United States) was developed to provide real-time feedback on catheter stability. This system uses an algorithm for the automated annotation of RF ablation applications based on objective, predefined parameters that incorporates catheter stability range of motion, catheter stability duration, impedance drop, and contact force measured at the catheter tip. Those parameters are recorded and updated 60 times/s throughout each energy application, and ablation tags are displayed accurately on the electroanatomic map on the basis of the locating coordinates of the catheter at each individual stable ablation site (Fig. 7.8). In addition, the tags are color-coded to provide the biophysical information of each individual ablation site. The ideal settings for an effective ablation lesion with this technique, however, have not been confirmed.^{38,39}

Fig. 7.8 Use of VisiTag Indicators of Tissue Contact During Ablation. The left atrium is shown from a posterior view in a case of circumferential pulmonary vein (PV) isolation for atrial fibrillation. (A) Manually designated standard dark red tags indicate sites of presumed ablation (where energy was delivered, but not necessary where a lesion was made). (B) Automated VisiTag markers indicate duration of catheter tip dwell at each site (*darker shades* = longer contact) and very small dots indicate where the catheter was at any time during radiofrequency energy delivery. No tag will be placed unless at least 20 seconds of consistent contact has been made. Note areas indicated by yellow arrows where VisiTag did not register enough ablation contact/time to warrant a tag, yet the operator believed an adequate lesion had been made. PV isolation was incomplete in both sets of PVs due to ablation gaps in these regions, that were subsequently effectively ablated.

TABLE 7.3 Strategies to Prevent Steam Pops During Cooled Radiofrequency Ablation

Ablation electrode temperature	Limiting electrode temperature to 40°C (for internally irrigated catheters) and 42°C–45°C (for externally irrigated catheters)
RF power output	Limiting RF power output especially in areas with firm tissue contact or thin chamber wall
Impedance monitoring	Titrating power output to prevent rapid or large (>15 Ω) reductions impedance during RF application
Contact force monitoring	Avoiding excessive catheter-tissue contact force
Intracardiac echocardiography	Visualization of microbubbles on ICE has been used as an indication of excessive tissue heating
Tissue temperature monitoring	Microwave radiometer-enabled catheter enables monitoring intramyocardial tissue temperature (investigational)
High-frequency ultrasound transducer	High-frequency ultrasound transducer integrated into the ablation catheter enables visualization of acute lesion formation in real time (investigational)

ICE, Intracardiac echocardiography; RF, radiofrequency.

Another method of trying to ensure atrial transmural lesions during pulmonary vein (PV) isolation is the force-time integral (FTI—St. Jude Medical, Sunnyvale, CA, United States), the product of the average contact force and time over which it was delivered at a given site. Some data suggest that a FTI of less than 400 gs was associated with recovery of venoatrial conduction after PV electrical isolation and thus a target of more than 400 gs appears to be useful. This does not account for the amount of power delivered, nor the contiguity of lesions. Other data suggest that tissue thickness is another variable to consider, and that 100 gs/mm tissue thickness is a more appropriate target. It should be pointed out that none of the methods used to try to ensure adequate ablation have been shown to decrease potential complications (such as collateral damage from too-deep ablation).

Electrogram-Gated Ablation

Even when catheter contact to target tissue appears stable, ablation catheter tip often slides along the cardiac tissue surface during regular heart motion. This lateral sliding motion spread delivered RF energy during a conventional ablation over a larger surface area of endocardium, reducing the efficiency of heating (less heating per unit area of tissue)

and limiting lesion depth. Studies in patients undergoing PV isolation showed that contact force remains highly variable during RF applications in spite of optimizing contact because of the ventricular (rather than atrial) contraction and respiratory movements of the heart.⁴⁰

A recent study described a novel method to compensate for cardiac motion by gating pulsed RF delivery to the sensed local electrogram, whereby RF energy delivery is limited to when the catheter is in contact with the local target (as judged by the quality of local electrogram) as opposed to the remainder of the cardiac cycle when the catheter may be sliding against the underlying myocardium. This method can potentially help improve lesion formation and avoid inappropriate energy delivery to surrounding tissue while the catheter is in motion. Nonetheless, electrogram gating can be difficult when the local electrogram is low amplitude or fractionated, when the electrogram changes in response to RF ablation, and when electric noise develops during energy delivery.⁴¹

Prevention of Steam Pops

Several approaches have been proposed to reduce the incidence of pop formation (Table 7.3).¹³

Ablation Electrode Temperature

For internally cooled catheters, it is recommended to limit electrode temperature to less than 40°C to prevent pop formation. In the setting of open irrigated catheters, however, electrode temperatures have shown to be correlate poorly with steam pop occurrence.

Power Output

Higher RF power output increases the risk of steam pops. However, a safe cut-off output has not been established, and power output limits have to be considered in relation with other factors, such as the degree of electrode cooling, catheter-tissue contact force, and cardiac wall thickness.

Impedance Monitoring

Large drops in impedance (greater than 15 Ω) during RF ablation are associated with increased risk of steam pops. In particular, the rate of impedance drop (greater than 1 Ω /s) appears to be a good predictor of steam pops. Power titration to prevent rapid reductions impedance can help improve safety.

Contact Force Monitoring

Increasing catheter-tissue contact force is associated with increased risk of steam pops, especially at thin target tissues that are not structurally well supported (such as the posterior LA wall). In one report, steam pops occurred with contact force of 40 g or more at RF output of 30 W, but with much lower contact force (10 g) at 50 W.

Intracardiac Echocardiography

Visualization of microbubbles on ICE has been used as an indication of excessive tissue heating that is predictive of char formation and steam pops during ablation and that warrants reduction or termination of RF energy. The presence of microbubbles on ICE is typically associated with a tissue temperature higher than 60°C and increased lesion size, and continued RF application after the appearance of the bubbles is usually followed by an increase in impedance. Of note, steam pops can be seen well on ICE, often with a sudden explosion of echocardiographic contrast.

Microbubble formation, however, is not a straightforward surrogate for tissue heating. The absence of microbubble formation clearly does not indicate that tissue heating is inadequate or that the power level should be increased, nor does the presence of scattered microbubbles indicate safe tissue heating. This marker is fairly specific for tissue heating as judged by tissue temperatures but is not routinely sensitive. Specifically, scattered microbubbles can occur over the entire spectrum of tissue temperatures, whereas dense showers of microbubbles appear only at tissue temperatures higher than 60°C. Scattered microbubbles can represent an electrolytic phenomenon, whereas dense showers of microbubbles suggest steam formation, with associated tissue disruption and impedance rises.

Furthermore, while identification of microbubbles on ICE as an indication of excessive tissue heating can potentially be helpful during ablation with nonirrigated and internally irrigated catheters, external irrigation produces visible bubbles, precluding the use of this method.

Tissue Temperature Monitoring

A novel microwave radiometer-enabled catheter is currently being tested for monitoring intramyocardial tissue temperature. The volume circumscribed by its radiometric antenna encompassed tissue present to a depth of 3 mm, which is the point of highest attained temperature during irrigated RF ablation. "Volumetric" temperature correlated well with tissue temperature measured at 3 mm depth. No steam pops occurred below a volumetric temperature of 89°C, especially when

associated with rapid temperature rise (greater than 1.5°C/s). Therefore limiting temperatures to less than 80°C can potentially prevent steam pop formation.¹³

High-Frequency Ultrasound

Recently, a high-frequency ultrasound transducer integrated into a novel RF ablation catheter enabled visualization of acute lesion formation in real-time. In experimental studies, the integrated near-field ultrasound was able to accurately visualize intramyocardial gas formation, which develops several seconds prior to a rise in tissue impedance measured from the ablation catheter. Therefore ultrasound can potentially detect steam formation prior to a potential pop, and if power delivery is terminated, intramyocardial steam can dissipate within the tissue without venting to the surface. Clinical evaluation is still pending.^{42,43}

Clinical Applications of Standard Radiofrequency Ablation

RF is the most frequently used mode of ablation energy and has become a widely accepted treatment for most atrial and ventricular arrhythmias. Studies have demonstrated the effectiveness of RF current in producing precise and effective lesions. Standard RF ablation catheters have tip electrodes with lengths ranging from 4 mm long and are available in sizes up to 10 mm long.

Nonetheless, several limitations exist, many of which center on how RF creates the tissue lesion. Current flow and energy delivery are critically dependent on a low-impedance electrode-tissue junction, but tissue desiccation, coagulation, and charring around the electrode can result in marked falls in conductivity. Temporal evolution of ablation lesions can potentially alter the immediate postablation substrate, by producing either lesion expansion (mediated in part by secondary myocyte loss from disrupted microcirculation) or lesion regression (resolution of edema and healing).

A major limitation of RF ablation is the relatively small depth of tissue injury produced by this technique. This can be attributed to the precipitous fall-off of direct tissue heating (volume heating) by the RF energy as the distance from the electrode-tissue interface increases. Deeper tissue layers can be ablated by heat conduction from the volume-heated source, but the maximum lesion depth is limited.

Because the success of RF catheter ablation in the clinical setting is sometimes limited by the relatively small size of the lesion, attempts have been made to increase the size of those lesions reliably and safely. One approach is to increase the size and surface area of the electrode. The RF power needs to be increased comparably to achieve a similar current density and temperature at the electrode-tissue interface, and the results are greater depth of volume heating and a larger lesion. In addition, using an electrode material with high thermal conductivity (such as gold) enhances passive cooling of the ablation electrode by the circulating blood pool, allowing for greater power delivery to create deeper lesions. Modifications to the RF energy delivery mechanism, including cooled catheters and pulsed energy, have also helped address some of these limitations. Moreover, investigation into alternative energy sources appears to be more promising, including microwave, ultrasound, laser, and cryoablation.

Delivery of RF energy on the epicardial surface generally requires an irrigated-tip catheter because there is otherwise no passive cooling of the electrode (outside the blood pool) and relatively little power can be delivered without being limited by temperature increases.

Clinical Applications of Cooled Radiofrequency Ablation

Several designs of the number and distribution of the holes around the open-irrigated electrode tip are currently available, aiming to provide

more homogeneous cooling over the tip surface and improve irrigation efficiency. Conventional open-irrigated electrodes have six irrigation holes circumferentially arranged at the distal end of the electrode. Another design adds another set of six ports at the proximal electrode end. A third design (ThermoCool SF, Biosense Webster) has 56 very small holes positioned along the entire distal electrode. A fourth design (Cool Flex, St. Jude Medical) involves laser-cut irrigation slits in a zigzag pattern in addition to four ports at the distal end of the tip.

However, from a clinical perspective, changing the electrode tip design of open-irrigated ablation catheters does not appear to have a significant impact on efficacy (lesion size) or safety.⁴⁴ Nonetheless, high irrigation rates during RF catheter ablation can be disadvantageous for patients with heart failure. Thus, catheter designs employing lower irrigation flow rates (e.g., ThermoCool SF) can be of particular value in these patients.⁴⁵

Potential Advantages of Cooled Radiofrequency Ablation

Excessive tissue surface heating invites coagulum formation and carbonization. These adverse effects can limit the RF lesion formation, thus making it difficult to produce lesions of sufficient depth in scar tissue or thickened ventricular walls. Active cooling of the ablation electrode by saline irrigation can help prevent overheating of the endocardium while allowing sufficient energy delivery to achieve a larger lesion size and depth.

Cooled tip catheters have several advantages. First, they allow the desired power to be delivered independent of local blood flow, and that results in increased lesion size. Second, they reduce the temperature of the ablation electrode as well as the temperature at the tissue interface, especially with the open-irrigation system, and that helps spare the endocardium and reduce the risk of coagulum and charring. Third, when compared with standard 8-mm-tip ablation catheters, a 3.5- to 4-mm irrigated electrode offers higher mapping accuracy while providing comparable ablation lesion size.

Cooled tip catheters are preferred (1) for long linear ablations (in the right or left atrium) and complex atrial arrhythmias (macroreentrant atrial tachycardia or AF), (2) when there is a high probability of encountering thick or trabeculated tissue, (3) for specific areas with low local blood flow (including the CS, particularly CS aneurysms, and pericardial space), (4) when ablating in the arterial circulation (to minimize the likelihood of arterial thromboembolism), and (5) for targets resistant to previous conventional ablation. Clinical trials have found irrigated tip catheters to be more effective than and as safe as conventional catheters for CTI ablation. Irrigated tip catheters also were found to be safe and effective in eliminating BT conduction resistant to conventional catheters, irrespective of the location, and they have been successfully used for PV isolation for treatment of AF. Irrigated tip catheters also

offer an advantage over conventional RF catheters in the case of scar-related VTs, by facilitating creation of larger and deeper lesions that can help eliminate intramyocardial or subepicardial reentrant pathways necessary for the VT circuit.

Internally cooled RF ablation is an attractive choice for use in pericardial ablation because no fluid is infused, and one need not worry about accumulation of pericardial fluid causing cardiac tamponade throughout the ablation procedure, although drainage of irrigant during open-irrigation RF ablation can be managed in this setting.

Potential Risks of Cooled Radiofrequency Ablation

Although creation of larger ablation lesions can improve the efficacy of ablation for some patients, particularly when the targeted arrhythmia originates deep to the endocardium and when large areas require ablation, it is associated with increased risk of damage to tissue outside the target region (Table 7.4). While increasing power delivery and convective cooling can create large lesions, lesion production is somewhat difficult to control. Active electrode cooling does not allow the temperature at the tip to be monitored, and thus some feedback about lesion formation is lost.

These concerns can be more pronounced with internal cooling as compared with open irrigation. Open irrigation cools the electrode and its direct environment, blood, and tissue surface. In contrast, with internal cooling, the main parameter affected by cooling is the temperature of the electrode, which further exaggerates the disparity between electrode and tissue temperatures. There can be minimal cooling of the direct electrode-tissue interface, but only at the true contact site between metal and tissue. A coagulum can also be formed, but it can go unnoticed because it does not adhere to a cool electrode and does not cause an impedance rise.

With open-irrigation catheters, extensive ablation often performed for AF and scar-related VT can result in substantial saline administration. Therefore management of the patient's volume status before, during, and after the procedure is crucial. This is also important during epicardial ablation, in which an obligatory fluid volume enters the pericardial sac and, if not intermittently or continuously evacuated, gradually results in cardiac tamponade. This complication can be prevented by having the side port of the introducer sheath attached to a suction bottle or gravity drain or by intermittent aspiration of accumulated fluid. Internal irrigation, on the other hand, has the advantages that no fluid is infused into the vasculature or pericardial space, and there is no possibility of embolization from the irrigation system.

Phased Radiofrequency Ablation

The phased RF AF ablation catheter family (Medtronic, Minneapolis, MN, United States) consists of three anatomically designed, multielectrode

TABLE 7.4 Comparison of Features of Ablation Electrodes

(Courtesy Medtronic, Minneapolis, MN, United States.)

catheters that deliver duty-cycled bipolar and unipolar RF energy: (1) the circular-shaped PV ablation catheter (PVAC, 10 platinum or 9 gold electrodes), used to create contiguous lesions in the PV antrum; (2) the Multi-Array Ablation Catheter (MAAC, 8 platinum electrodes), used to create linear lesions in the LA and to target fractionated electrograms; and (3) the Multi-Array Septal Catheter (MASC, 12 platinum electrodes), used to ablate tissue along the interatrial septum (Fig. 7.9). Each platinum electrode has a thermocouple on the side of the electrode in contact with the tissue.^{4-6,33}

A multichannel duty-cycled RF ablation generator (GENius Multi-Channel RF Generator, Medtronic) contains 12 independently controlled RF generators, and is capable of delivering RF energy to each electrode independently. RF energy can be delivered in either bipolar (between contiguous electrodes) or unipolar (from the electrode to the ground pad) current by a phase difference between the channels (Fig. 7.10). When “in phase,” there is no voltage difference and, thus, no current flow between neighboring electrodes, so only unipolar energy is delivered between each electrode and the ground pad. When the voltages for the two adjacent electrodes are “out of phase,” interelectrode voltage difference results in bipolar RF delivery.⁴⁻⁶

Power regulation is achieved through cycling the RF energy on and off (duty-cycled RF), rather than voltage control (see Fig. 7.10). The time period with no RF delivery allows accurate temperature monitoring and provides time for the electrode to cool between RF bursts. Unipolar RF delivery results in deeper lesions, while bipolar application creates shallower but longer and contiguous lesions between electrodes. The generator has five preset energy settings: bipolar, unipolar, and three ratios of bipolar/unipolar energy: 4:1 (80% bipolar, 20% unipolar), 2:1 (66% bipolar, 34% unipolar), and 1:1 (50% bipolar, 50% unipolar). The choice of bipolar-to-unipolar energy delivery ratio is based on desired lesion depths (determined by the unipolar energy ratio) and fill in between adjacent electrodes (determined by bipolar RF ratio). Unipolar RF delivery creates the deepest lesions, followed by 1:1, 2:1,

4:1 and bipolar RF application, with the latter causing the shallowest lesions.

A maximum of 10 W of RF energy is delivered (using a closed-loop power control generator) to individual electrodes in a temperature controlled mode to achieve a target temperature (nominally 60°C). Cooling of the nonirrigated electrodes (in order to deliver sufficient power for lesion generation without producing char or coagulum) is facilitated by the combined effect of energy duty cycling, convective blood flow, and increased temperature accuracy to maintain adequate electrode cooling.⁴⁶ In addition, gold electrodes (for PVAC-Gold catheter) offer more than four times better thermal conductivity than that of platinum, thereby providing faster cooling and more precise temperature control.

One advantage of this approach is the simultaneous application of RF energy across an electrode array, intended to create contiguous lesions near an anatomical structure. In addition, the multielectrode catheters allow selective mapping and ablation through any or all electrodes as required.

The majority of available data relate to PV isolation with the PVAC in patients with paroxysmal AF. The PVAC isolation technique demonstrated high acute procedural success and significantly shorter procedure and fluoroscopy times relative to other AF ablation methods, without the need for a 3-D mapping system. However, initial reports showed an alarmingly high incidence of asymptomatic cerebral embolism when using PVAC (fivefold greater as compared with conventional irrigated RF delivery or cryoballoon for PV isolation).^{4,47,48} This is likely related to electrode overheating, which was predominantly found when electrodes 1 and 10 were in close proximity during ablation (especially bipolar current) and lack of tissue contact. The incidence of manifest and silent cerebral complications has fallen significantly in recent reports, after implementation of aggressive periprocedural anticoagulation regime (uninterrupted anticoagulation with warfarin and activated clotting time greater than 350 seconds), disconnection of either electrode 1 or

Fig. 7.10 Phased and Duty-Cycled Radiofrequency (RF) Ablation. In phased RF (*left*), energy can be delivered in a unipolar mode, a bipolar mode, or a combination. In the unipolar mode, energy is delivered between the catheter electrodes and a ground electrode on the patient's back, providing lesion depth. In the bipolar mode, energy is delivered between adjacent catheter electrodes, providing lesion continuity. A combination of the two modes can be used to create lesions of varying size. In duty-cycled RF energy delivery (*right*), RF energy is cycled on and off to allow the catheter electrodes to cool without saline irrigation. The length of the "on" time is regulated to reach and maintain the target temperature. The time period with no RF delivery allows accurate temperature monitoring and provides time for the electrode to cool between RF bursts. (From Barnett AS, Bahnson TD, Piccini JP. Recent advances in lesion formation for catheter ablation of atrial fibrillation. *Circ Arrhythm Electrophysiol*. 2016;9:e003299.)

10, and improvements in catheter design and software regulations of the RF generator.^{49–51} More recently, the second-generation phased RF catheter, PVAC Gold, was introduced, which eliminates electrode 10 (to avoid the formation of emboli through the interaction of electrodes 1 and 10) and uses gold electrode material instead of platinum (to improve electrode cooling) (Fig. 7.11).^{4,52,53}

nMARQ Ablation System

The nMARQ catheter (Biosense Webster, Diamond Bar, CA, United States) is a decapolar mapping and ablation catheter with individually irrigated platinum electrodes (3 mm long, with interelectrode spacing of 4 mm). Each electrode possesses a thermocouple and holes for irrigation. The multichannel RF generator (nMARQ, Biosense Webster) is capable of delivering independently unipolar or bipolar RF energy to a maximum of 10 electrodes simultaneously (Fig. 7.12).

RF energy is applied in a temperature-controlled mode and energy delivery can be individually arranged over each combination of the 10 electrodes in unipolar mode (maximum 25 W and 45°C) or bipolar mode between two adjacent electrodes (maximum 15 W and 45°C). During ablation, a continuous flow of heparinized saline fluid is provided by a cooling pump with 60 mL/min for irrigation of all electrodes.^{7–9}

The conceptual advantage of the nMARQ ablation system over the previous multielectrode ablation systems is the presence of irrigation, which theoretically provides the same benefit that it brought to focal RF ablation: lowering the electrode temperature to reduce charring and allow higher power delivery. However, the risk of deep RF lesions and consequent esophageal injury remains a concern. The nMARQ catheter

was recalled from clinical use due to issues with the thermocouple and reporting of three deaths, of which two were confirmed to be due to atrioesophageal fistula.^{54,55}

CRYOABLATION

Biophysics of Cryothermal Energy

If a gas is compressed at high pressure and then is allowed to expand suddenly in region of low pressure, the temperature of the gas decreases. This phenomenon is known as the Joule-Thomson effect. Compression of the gas decreases intermolecular distances and, as a result, the forces of attraction between the molecules become appreciable. During expansion, gas molecules move far away from each other, but energy is required to counteract the intermolecular attraction forces. Heat energy of the molecules of the gas is utilized for this purpose, a process that results in reduction of gas temperature.⁵⁶

For intravascular cryoablation, a precooled, compressed liquid refrigerant (nitrous oxide) is delivered under constant pressure from the console to the tip of the ablation catheter. Cryoablation catheters have a terminal segment with sudden luminal widening (expansion chamber) (Fig. 7.13). In cryoballoon catheters, the balloon acts as the expansion chamber. Decompression and expansion of the liquefied nitrous oxide (accelerated liquid-to-gas phase change) as it passes into the expansion chamber absorbs heat from the surrounding tissue (based on the Joule-Thomson effect), thereby cooling the surface. The vaporized refrigerant then is vacuumed back to the console via a second coaxial return lumen within the shaft of the catheter. Nitrous oxide has a boiling

Fig. 7.11 Pulmonary Vein Ablation Catheter (PVAC) Design. Design differences between PVAC Gold (*top panel*) and PVAC (*lower panel*) are shown. Electrodes were switched to gold from platinum, number of electrodes reduced to 9 for PVAC Gold from 10 with PVAC, interelectrode spacing increased from 3.00 to 3.75 for PVAC Gold, and PVAC Gold includes a 20-degree forward tilt of the array. (From Weber S, Höher M, Schultes, D. First results and follow-up of a second-generation circular mapping and ablation catheter. *J Interv Card Electrophysiol.* 2016;47:213–219.)

temperature of -88.4°C , and is capable of rapid cooling of the catheter tip to below -75°C .^{56,57}

The effect produced by cryothermal ablation is the result of a temperature gradient occurring at the electrode-tissue interface (i.e., heat is extracted from the tissue by the cooled catheter tip), which causes tissue freezing and ice formation, both intracellularly and extracellularly. Whereas extracellular ice yields destruction due to solute effects (see below), damage caused by intracellular ice is mediated mainly by shearing force. The degree of tissue freezing and formation of ice only extracellularly versus both inside and outside the cell greatly depend on the minimum temperature reached, the duration of energy application, and the temperature time constant. The temperature time constant indicates the course of the descent of temperature to the target temperature, and a shorter value (expressed in seconds) identifies a more effective application. Important modulatory variables that can affect tissue damage produced by cryoablation include firmness of the catheter-tissue contact, tip temperature, freeze duration, and blood flow.⁵⁶

Initially, mild hypothermia (32°C) impacts the transport capacity of the ion pumps and, consequently, decreases action potential amplitude, prolongs action potential duration, and impairs conduction. With mild freezing temperatures (-10°C to -25°C), extracellular ice forms, resulting in cell dehydration, more acidic intracellular pH, and ionic imbalances, leading to membrane injury and cessation of cardiac electrical activity. The degree of permanent cellular damage at these tissue temperatures is directly related to duration of freezing. On the other hand, rapid extreme freezing (tissue temperatures colder than -50°C) results in intracellular ice formation and near instantaneous permanent tissue injury.^{56,57}

At the electrode-tissue interface, the coldest area is the one adjacent to the catheter tip, where functional effects of energy delivery are observed early (Fig. 7.14). Conversely, the less cooled area is the one at the periphery of the cryolesion, whose dimensions can also vary according to the duration of freezing. Because of limited cooling of the outer limit of the lesion (both in time and temperature), this region is less likely to incur irreversible damage. As a consequence, the effects obtained late during cryothermal energy application are likely to be reversible early on rewarming, and therefore any expected functional modification induced by cryoenergy should occur early (usually within the first 30 seconds of the application) to obtain a successful and permanent ablation of a given arrhythmogenic substrate.

Pathophysiology of Lesion Formation by Cryoablation

The mechanisms underlying lesion formation by cryoenergy are twofold: direct cell injury caused by ice formation and vascular-mediated tissue injury. The mechanisms of cellular death associated with tissue freezing involve immediate cellular effects, as well as late effects that determine the lesion produced.⁵⁷

Extracellular Ice Formation (Solution Effect Injury)

Direct cellular injury results from ice formation. Ice forms only extracellularly when the tissue is cooled to mild temperatures (0°C to -20°C) and results in hypertonic stress (the extracellular environment becomes hyperosmotic) through freeze concentration of solutes. This creates a diffusion gradient that causes shift of water from the intracellular to the extracellular space, net movement of H^{+} ions out of the cell, and the migration of solute ions into the cell. These changes ultimately

Red-colored electrodes indicate RF ablation on. CS, Coronary sinus catheter; Eso, esophageal temperature probe. (From Deneke T, Schade A, Müller P, et al. Acute safety and efficacy of a novel multipolar irrigated radiofrequency ablation catheter for pulmonary vein isolation. *J Cardiovasc Electrophysiol.* 2014;25:339–345.)

cause cell shrinkage, increased intracellular saline concentration with a reduction in intracellular pH, which result in damage to the plasma membrane cellular constituents and impairment of enzyme function.

These effects are reversible when rewarming is achieved within a short period (30 to 60 seconds). However, extended periods of extracellular freezing result in cellular death, and rewarming then results in cellular swelling sufficient to disrupt cellular membranes.⁵⁷

Intracellular Ice Formation

When the tissue is cooled to below -40°C , especially if cooling occurs rapidly, ice forms both extracellularly and intracellularly. Intracellular ice results in major and irreversible disruption of organelles, leading to cellular death. Although ice crystals do not characteristically destroy cell membranes, they compress and deform nuclei and cytoplasmic components. Mitochondria are particularly sensitive to ice crystals and

Fig. 7.13 Schematic Diagram Demonstrating the CryoCath Freezor Cryocatheter Internal Design. (Courtesy CryoCath Technologies, Montreal, Canada.)

Fig. 7.14 Depth of Maximum Tissue Injury With Irrigated-Tip Radio-frequency (RF) Versus Cryotherapy. With irrigated RF (*left*), the maximum tissue heating occurs at some tissue depth because of cooling at the surface. With cryotherapy (*right*), the maximum effect is at the endocardial surface.

are the first structures to suffer irreversible damage. Furthermore, intracellular ice can propagate from one cell to another via intercellular channels, thus potentially resulting in lesion growth.

Importantly, cellular injury, disruption of membranous organelles in particular, is enhanced on cellular thawing. Rewarming causes recrystallization of ice (−20°C to −25°C), whereby intracellular ice crystals fracture and reform into larger crystals that extend mechanical shear forces and cellular destruction. Further, thawing of ice creates a transient hypotonic environment with consequent shift of water from the extracellular to the intracellular space, leading to severe swelling of the cell and membrane rupture. Cellular injury can be extended by repeated freeze-thaw cycles. Final rewarming evokes an inflammatory response to released cellular constituents and reperfusional hemorrhage, leading to tissue repair and eventual dense scarring. The size of ice crystals and their density depend on the proximity to the cryoenergy source, local tissue temperature achieved, rate of freezing, and surface area in contact with freezing temperatures.^{57,58}

TABLE 7.5 Determinants of Cryoablation Lesion Size

Ablation electrode temperature	Lesion size increases with lower electrode temperature
Freezing duration	Lesion size increases longer freezing duration
Freezing rate	Lesion size increases with faster freezing rate
Thawing rate	Lesion size increases slower thawing rate
Electrode-tissue contact	Lesion size increases with improved tissue contact
Electrode length	Lesion size increases with larger electrode length
Electrode orientation	Lesion size increases with parallel electrode orientation
Convective warming	Lesion size decreases with increased local blood flow due to increased convective warming

The zone of intracellular ice formation, the cornerstone of cryoablation and permanent tissue damage, is typically located within the core of the cryogenic lesion adjacent to the ablation electrode. Tissues located at a distance from the electrode are exposed to lesser degrees of cooling, resulting in a zone of only extracellular ice formation where incomplete tissue damage is experienced. Tissues farthest from the tip only experience hypothermia, resulting in reversible damage.

Vascular-Mediated Tissue Injury

Tissue freezing results in vasoconstriction, hypoperfusion, and ischemic necrosis. Subsequent tissue rewarming produces a hyperemic response with increased vascular permeability and edema formation. Endothelial disruption within the frozen tissue is also observed and results in platelet aggregation, microthrombi, and microcirculatory stagnation within the lesion.

Chronic Cryogenic Lesion Formation

In the final phase of cryoinjury, replacement fibrosis and apoptosis of cells near the periphery of frozen tissue give rise to a mature lesion within weeks. Typically, these lesions display a well circumscribed necrotic core (corresponding to the frozen volume within the critical isotherm), which eventually becomes replaced by dense homogeneous fibrosis, with sharply demarcated borders.⁵⁷ Characteristically, cryoablation does not cause collagen denaturation or contracture, which helps preserve tissue ultrastructural integrity, and matrix architecture tensile strength, and minimize tissue shrinkage. In addition, the degree of endothelial damage and overlying thrombus formation are substantially less than that associated with standard RF lesions. Of note, higher levels of biomarkers of necrosis (creatinine kinase [CK], CK-MB, and Troponin I) were observed in cryoablation when compared to RF ablation.^{59,60}

Determinants of Cryogenic Lesion Size

During cryoablation, lesion size and tissue temperature are related to convective warming, electrode orientation, electrode contact pressure, electrode size, refrigerant flow rate, and electrode temperature (Table 7.5). Lesion sizes during catheter cryoablation can be maximized by use of larger ablation electrodes with higher refrigerant delivery rates.

In contrast to RF ablation, cryoablation in areas of high blood flow can result in limited tissue cooling and smaller lesion sizes because of convective warming.⁵⁶ Conversely, cryoablation lesion size can be maximized in areas of low blood flow. A horizontal electrode orientation to the tissue and firm contact pressure also enhance lesion size, likely due

to increasing tissue contact area and reducing electrode exposure to the warming effect of the surrounding blood pool.

As noted, duration of freezing is an important determinant of the extent of tissue damage. Longer freezing durations not only enhance cell injury but also provide time for the tissues at the periphery of the cryolesion (exposed to slower cooling rate) to attain the lowest achievable temperature.⁶¹ Importantly, the rate of both freezing and thawing can affect lesion size. Rapid freezing rates are associated with larger volumes of cryoablation lesion. In addition, prolonged rewarming (i.e., slower thawing rate) increases the time of cell damage and lesion size. Slow thawing subjects the tissue to prolonged hypotonic stress, cellular edema, and ice recrystallization. The optimal freeze/thaw cycle employs fast freezing rate (approximately 100°C/min), followed by a slow thawing rate (optimally by allowing passive rewarming by natural body heat and blood flow) to maximize tissue injury. Repeating the freeze-thaw cycle also extends lesion boundaries.^{56,62}

Larger electrode sizes allow greater refrigerant flow rates as well as larger electrode surface area in contact with the tissue and, hence, larger lesions. The 6- and 8-mm electrode-tip cryocatheters produce ablation lesions of similar depth that are more than two- and threefold larger than 4-mm catheters, respectively. Despite larger lesions, endothelial cell layers remain intact and devoid of thrombosis.

Surface areas and volumes can be particularly sensitive to catheter tip-to-tissue contact angles with larger electrodes. As such, particular attention in catheter orientation is required with 8-mm electrode-tip cryocatheters to produce desired lesions.

Technical Aspects of Cryoablation

The cryoablation procedure is often performed in two steps. First, “cryomaps” are obtained by moderate cooling of tissue (electrode-tissue interface temperature approximately -28°C to -32°C), which is accompanied by reversible suppression of cellular electrical activity without inducing histologically identifiable damage. Second, cryoablation cools the selected cryomapped pathways to much lower temperatures (electrode-tissue interface temperature below -68°C) and causes intracellular ice formation and irreversible tissue injury.⁵⁷

Cryomapping

Cryomapping is designed to verify that ablation at the chosen site will have the desired effect and to ensure the absence of complications (i.e., to localize electrical pathways to be destroyed or spared). This procedure generally is performed using various pacing protocols that can be performed during cryomapping (or ice mapping) at -32°C . At this temperature, the lesion is reversible (for up to 80 seconds), and the catheter is stuck to the adjacent frozen tissue because of the presence of an ice ball that includes the tip of the catheter (cryoadherence). This permits programmed electrical stimulation to test the functionality of a potential ablation target during ongoing ablation and prior to permanent destruction. It also allows ablation to be performed during tachycardia without the risk of catheter dislodgment on termination of the tachycardia.

In the cryomapping mode, the temperature is not allowed to drop to less than -30°C , and the time of application is limited to 60 seconds. Formation of an ice ball at the catheter tip and adherence to the underlying myocardium are signaled by the appearance of electrical noise recorded from the ablation catheter's distal bipole. Once an ice ball is formed, programmed stimulation is repeated to verify achievement of the desired effect. If cryomapping does not yield the desired result within 20 to 30 seconds or results in unintended effect (e.g., AV conduction delay or block), cryomapping is interrupted, to allow the catheter to thaw and become dislodged from the tissue. After a few seconds, the catheter may be moved to a different site and cryomapping repeated.

Cryoablation

When sites of successful cryomapping are identified by demonstrating the desired effect with no adverse effects, the cryoablation mode is activated, in which a target temperature lower than -75°C is sought (a temperature of -75°C to -80°C is generally achieved). The application is then continued for 4 to 8 minutes, thus creating an irreversible lesion (although recent experimental evidence suggests that single 2-minute and 4-minute application times result in catheter ablation lesions of similar size using the modern cryoablation system) (eFig. 7.4).⁶²

If the catheter tip is in close contact with the endocardium, a prompt drop in catheter tip temperature should be observed as soon as the cryoablation mode is activated. A slow decline in catheter tip temperature or a very high flow rate of refrigerant during ablation suggests poor electrode-tissue contact. In such cases, cryoablation is interrupted, and the catheter is repositioned.

Cryoballoon Ablation

The cryothermal balloon ablation system (Arctic Front, Medtronic, Minneapolis, MN, United States) consists of a nondeflectable, 10.5 Fr catheter with distally mounted coaxial double inner-outer cooling balloons (“balloon within a balloon,” outer balloon maximum diameter, 23 or 28 mm) specifically designed for PV isolation (Fig. 7.15). The balloon acts as the expansion chamber as the liquid nitrous oxide converts to gas. During cryotherapy, temperature is monitored via a thermocouple located at the inner balloon.^{56,57,63}

The cryoballoon is deployed at the ostium of targeted PV and cryoenergy is delivered over the occluding balloon system to create circumferential lesions around the PV ostium. This design helps limit the convective warming effects of the high blood flow at the PV ostium (which can limit lesion size and ablation efficacy), as well as shorten the lengthy procedure times required for circumferential point-by-point cryoablation around the PV ostia with the standard steerable cryocatheters.^{56,57,63,64}

Fig. 7.15 Cryothermal Balloon Catheter. (Courtesy Medtronic, Inc., Minneapolis, MN, United States.)

eFig. 7.4 Cryoablation Lesions With 2-Minute and 4-Minute Application Times. Ablation lesions are shown 1 month after cryothermal applications in the left ventricle (in canine model) of 2-minute (A) and 4-minute (B) duration. Lesions were stained with Masson's trichrome and slides were scanned for visualization and analyses. The ablation lesions are sharply demarcated from the surrounding myocardium, with preserved ultrastructural tissue integrity. (From Bessière, F, Dubuc M, Andrade J, et al. Focal transcatheter cryoablation: is a four-minute application still required? *J Cardiovasc Electrophysiol.* 2017;28:559–563.)

Clinical Advantages of Cryoablation

The use of cryoablation in the EP laboratory provides some distinct advantages not seen with conventional RF ablation. The slow development of the cryolesion (approximately 240 seconds), although time-consuming, enables the creation of reversible lesions and modulation of lesion formation in critical areas. As noted, cryomapping allows functional assessment of the efficacy and safety of a putative ablation site during ongoing ablation and prior to permanent destruction. This offers a safety advantage when ablation is performed close to critical structures such as the AVN or His bundle (HB).

Compared with standard RF lesions, cryolesions are associated with substantially less endothelial disruption, less platelet activation, and lower thrombogenic tendency. Therefore the risk of coagulum formation or charring is less than with RF ablation (see Table 7.4). Furthermore, cryoablation results in dense homogeneous fibrotic lesions with a well-demarcated border zone and does not cause collagen denaturation or contracture (which helps preserve tissue ultrastructural integrity), in contrast to the RF hyperthermic effects. Therefore cryothermal energy application in close proximity to the coronary arteries (e.g., during epicardial ablation) or in venous vessels (CS, middle cardiac vein, and PVs) is less likely to result in damage, perforation, or chronic stenosis of their lumen.⁵⁷

The cryoadherence effect results in the formation of a very focal lesion because of fixed and stable tip electrode contact to adjacent frozen tissue throughout the whole application. This has a particular safety advantage, especially for ablation in the proximity of critical areas, such as the AVN and HB. In addition, cryoadherence augments catheter stability throughout the energy application, even when sudden changes in heart rhythm that can potentially displace the ablation catheter (e.g., tachycardia termination) occur. At the same time, cryoadherence does not compromise safety. On discontinuation of cryothermal application, the defrost phase is fast (within 3 seconds), and the catheter can be immediately disengaged from the ablation position.

Cryothermal energy application is characterized by the absence of pain perception in nonsedated patients, likely because hypothermic exposure desensitizes the nerves in the injured area secondary to decreased ion transport. In fact, cryoablation can be performed without analgesia. Occasionally, a light sense of cold or headache is perceived as minor discomfort. This characteristic can be particularly useful in younger and pediatric patients.

Clinical Applications of Cryoablation

Currently, two different types of cryoablation catheters are available: traditional-tip ablation catheters and balloon catheters. The traditional catheters (Freezor Max, Medtronic, Minneapolis, MN, United States) are used for focal ablation. These steerable catheters come with 4-, 6-, or 8-mm-long-tip electrodes, and have three additional proximal ring electrodes for EP recordings as well as a proximal thermocouple.⁶⁴

The cryoballoon catheter is specifically designed for PV isolation. The second generation of cryoballoon catheter offers twice the number of refrigerant spray ports and more homogeneous cooling effect on the distal hemisphere of the balloon (see Chapter 15).^{56,57,63}

As noted, catheter-based cryoablation can have specific advantages over RF catheter ablation, including greater safety as a result of greater catheter stability, reduced risk of systemic embolization, low propensity for thrombus formation and endothelial disruption, and preservation of ultrastructural tissue integrity. As a result, cryoablation has quickly been adapted for specific arrhythmogenic substrates in which RF has specific limitations that can potentially be overcome by cryotherapy. However, it is unlikely that cryoablation will replace standard RF ablation in unselected cases.

Atrioventricular Nodal Reentrant Tachycardia

So far, slow pathway ablation for AVNRT by cryothermal energy represents the largest experience in the clinical application of focal cryoablation. Cryoablation can be of particular safety advantage in patients with AVNRT. Not a single case of persistent AV block has been reported, even when using large-tip cryocatheters, and despite the fact that transient AV block occurs in up to 2% to 23% of patients during cryomapping at -30°C or during cryoablation at -75°C .⁶⁵ However, long-term success rates remain lower than that of RF ablation. In a meta-analysis of cryoablation versus RF ablation for AVNRT, cryoablation was associated with a lower risk of permanent AV block (0% vs. 0.75%) but higher risk of long-term AVNRT recurrence (9.7% vs. 3.8%) and longer total procedure time (111.7 minutes vs. 81.2 minutes).^{66–68}

According to current data, cryothermal energy is a valuable and useful alternative to RF energy to treat patients with AVNRT. The absence of permanent inadvertent damage of AV conduction makes this new technology particularly useful for patients with difficult anatomy, after an unsuccessful prior standard ablation procedure, in pediatric patients, and in patients in whom even the small risk of AV block associated with RF ablation is considered unacceptable. Cryoablation can be of particular advantage in several situations, including posterior displacement of the fast pathway or AVN, a small space in the triangle of Koch between the HB and the CS ostium, and the need for ablation to be performed in the midseptum. However, given the high success rate and low risk of RF slow pathway ablation, it can be difficult to demonstrate a clinical advantage of cryoablation over RF ablation in unselected AVNRT cases.

Bypass Tracts

Cryothermal ablation of BTs in the superoparaseptal and midseptal areas, both at high risk of complete permanent AV block when standard RF energy is applied, is highly safe and successful (eFig. 7.5). Cryoablation can also be successfully and safely used to ablate selected cases of epicardial left-sided BTs within the CS, well beyond the middle cardiac vein, once attempts using the transseptal and transaortic approaches have failed. However, the experience with cryoablation in unselected BTs is more limited and less satisfactory; this likely is related to multiple factors, including the learning curve and the smaller size of the lesion produced by cryoablation. Also, the cryocatheter is not yet as steerable as the conventional RF catheter. Catheter stiffness and limited maneuverability can limit proper positioning of the catheter tip and potentially result in tissue trauma and transient mechanical AV or BT block. Furthermore, the large electrode spacing decreases the specificity of mapping of the BT. In addition, all the distinguishing features of cryothermal energy, which are optimal for septal ablation, are less important for ablation of BTs located elsewhere.⁶⁹

In recent series, the acute success rate of cryoablation of BTs in the superoparaseptal and midseptal regions exceeded 90% (range, 60% to 100%). However, recurrence rates after initially successful cryoablation remain high (occurring in up to 20% of patients), and overall success rates have been lower than those with RF ablation of BTs. It is, however, important to note that alternatives for elimination of up to 17% of those BTs are limited by a prohibitive risk of AV block with RF ablation. Further, patients often prefer a strategy to minimize the risk of procedural AV block even when associated with a lower rate of procedural success.^{69–71}

Typical Atrial Flutter

Complete CTI block can be achieved by cryothermal ablation. An advantage of using cryothermal energy for the ablation of typical AFL is the absence of pain perception related to energy application. However, although the acute success rates of cryoablation appear comparable to

eFig. 7.5 Cryoablation of a Para-Hisian Bypass Tract (BT). Right anterior oblique fluoroscopic view of cryoablation catheter (*Cryo*) position and ECG and intracardiac recordings during cryoablation of para-Hisian BT. The first two QRS complexes at left are preexcited, with the second QRS complex (*blue arrow*) less so than the first (*red arrow*), as cryoablation begins to affect pathway conduction. Preexcitation disappears afterward. The ablation recordings at bottom are severely disrupted by the delivery of cryoenergy. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *Abl_{uni}*, unipolar ablation site; *CS*, coronary sinus; *CS_{dist}*, distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RA*, right atrium; *RV*, right ventricle; *RVA*, right ventricular apex.

those for RF ablation (89% vs. 91%), long-term cryolesion durability is inferior to that in patients treated with RF ablation, as evidenced by the higher recurrence rate of symptomatic, ECG-documented AFL (10.9% vs. 0%), and higher asymptomatic CTI conduction recurrence rates (23.4% vs. 15%). In addition, compared with RF ablation, cryoablation is associated with significantly longer procedure times, driven mainly by the longer duration of each cryoablation (4 minutes) compared with RF ablation (up to 60 seconds).

Pulmonary Vein Isolation

In view of the characteristics mentioned earlier, cryothermal energy ablation can be considered an ideal and safer energy source for PV isolation, and the incidence of PV stenosis and thromboembolic events is expected to be dramatically reduced compared with RF ablation. On the other hand, cryothermal injury is sensitive to surrounding thermal conditions. The high flow of the PVs can present a considerable heat load to cryothermal technologies, which can limit the size and depth of the lesion produced by cryothermal energy at the ostium of the PV. Unlike point-by-point RF ablation, cryoenergy cannot be modified selectively in different regions around the PVs. Also, variations in PV anatomy can influence the effectiveness of cryoballoon ablation, likely due to the difference in the venous seal obtained being dependent on the PV ostial shape and cryoballoon alignment.^{56,57,63,64}

Studies comparing cryoablation with open-irrigated RF ablation in the setting of paroxysmal AF ablation demonstrated statistical equivalence between the two technologies in terms of safety and efficacy. Limited data also suggest comparable outcomes in patients with persistent AF, with a comparable rate of freedom from AF at 1 year after a single RF procedure (42% to 67%). Phrenic nerve injury is significantly more common following second-generation cryoballoon ablation (approximately 3%) as compared to RF ablation. Nonetheless, this rate is much less than that observed with the first-generation cryoballoon system (up to 13%). Despite the hope that cryoablation would not cause significant esophageal damage and thus could prevent formation of atrioesophageal fistulae, these have nonetheless been reported with standard usage of the cryoballoon.^{72–76}

Focal Atrial Tachycardia

Cryoenergy can be particularly valuable in ablating atrial foci located close to the AVN or within venous structures.

Ventricular Tachycardia

Data regarding cryoablation for VT remain scant. Small reports described feasibility and success of cryoenergy for ablation of outflow tract VT. In addition, cryothermal energy can be of potential advantage in percutaneous subxiphoid epicardial ablation of VT because of less potential damage to the epicardial coronary arteries. The reduced heat load in the pericardial space related to the absence of blood flow limits RF energy delivery but can be to the advantage of cryoablation, with the possibility of producing larger transmural lesions.⁷⁷

LASER ENERGY

Biophysics of Laser Energy

Light amplification by stimulated emission of radiation (laser) produces a monochromatic (narrow-frequency range) phase-coherent beam at a specific wavelength (Fig. 7.16). This beam can be directed for a specific duration and intensity, and as it penetrates the tissue, it is absorbed and scattered. The photothermal effect occurs with the absorption of photon energy, thus producing a vibrational excited state in molecules (chromophores). By absorbing this energy, the tissue is heated and a lesion is created (i.e., tissue injury is thermally mediated).

Fig. 7.16 Laser Balloon Aiming Beam. (Courtesy CardioFocus, Marlborough, MA, United States.)

Laser energy can be delivered in a continuous or a pulsed mode. Laser energy is selectively absorbed by the tissues over several millimeters, and it decays exponentially as it passes through the tissue secondary to absorption and scatter, the extent of which depends on laser beam diameter and the optical properties of the tissue. Lesion size is determined by the extent of light diffusion and heat transport.

Three major laser systems are used: argon laser, neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, and diode laser. Argon laser uses a gaseous lasing medium (argon), which emits light at a wavelength of 500 nm. With this system, the light energy is absorbed rapidly in the first few millimeters of tissue, with resulting surface vaporization with crater formation. Nd:YAG laser uses a solid lasing medium (Nd:YAG), which emits energy at a wavelength of 1060 to 2000 nm in the infrared spectrum. This system is associated with significant scatter in tissue. It causes more diffuse and deeper tissue injury and results in photo-coagulation necrosis. On the other hand, diode laser uses semiconductors and emits energy at a wavelength of 700 to 1500 nm (near-infrared). To an extent, diode lasers can be customized to effect different depths of damage (mid-myocardial vs. endo- or epicardial, for instance).

Clinical Applications of Laser Energy

Early studies of laser ablation used a high-energy laser that carried a high risk of crater formation and endothelial damage. These studies focused on the intraoperative use of lasers in the ultraviolet and visible range (308- to 755-nm wavelength), and they appeared to show effectiveness of the lesions placed. Laser energy can also be delivered along the entire length of a linear diffuser, which provides uniform linear laser ablation and a superior transmural lesion when compared with previous end-firing optical delivery systems. The use of the linear diffuser in combination with lasers in the infrared or near-infrared wavelength (800 to 1100 nm) is currently under investigation.

Laser energy is absorbed by blood; as a consequence, its application directly into blood results in thrombus formation. This limitation is obviated by application of laser energy through a fluid-filled balloon positioned against the tissue to provide a bloodless interface for ablation. Laser energy has been used with balloon technology for PV isolation. The most recent generation of this balloon catheter is a nonsteerable, variable-diameter, compliant balloon (HeartLight, CardioFocus, Marlborough, MA, United States). The central shaft of the balloon contains a 2-Fr endoscope that provides real-time visualization of the face of the balloon: both the tissue and blood in contact with the balloon. Also,

within the central shaft are additional lumens for circulating deuterium dioxide (D_2O) to cool the balloon, and a maneuverable optical fiber that generates a 30° arc/spot of both nonablative visible light and near-infrared ablative light energy.^{78–80}

The laser balloon is inserted at the PV antrum through a 12 Fr deflectable sheath. Varying balloon inflation pressure allows for adjustment to the individual PV anatomy to optimize PV occlusion and maximize balloon-tissue contact. The balloon is filled with a mixture of contrast and D_2O and irrigated internally at 20 mL/min to minimize absorption of laser energy. Once the balloon is deployed, the endoscope enables real-time visualization of the face of the balloon at the targeted PV antrum and monitoring for the intrusion of blood into the space between the balloon and the tissue.⁷⁹

The arc generator consists of an optical fiber located within the central shaft that projects a 30-degree arc of light onto regions of balloon-tissue contact guided by an endoscopic view of the PV antrum (areas of balloon-tissue contact are visualized as blanched white, whereas contact with blood is visualized as red). This arc serves as an aiming beam for laser delivery and can be maneuvered along the balloon face with endoscopic visualization, to facilitate individual lesion application in an anatomically flexible lesion design that adapts to the highly variable PV anatomy. Once the proper location is identified, a diode laser is used to deliver laser energy at 980 nm. The laser fiber can be advanced or withdrawn to shift the site of lasing along the longitudinal axis of the catheter, and can be rotated to any location on the face of the balloon. Lesions are deployed in a point-by-point fashion in a circumferential, contiguous, and overlapping manner around the PV; each individual ablation lesion covers 30 degrees of a circle.^{79,80}

Laser energy is delivered at power output of 5.5 to 12 W for 20 to 30 seconds, depending on the thickness of tissue or the proximity of the esophagus. To minimize thrombus formation risk, a 5.5-W energy is applied for 30 seconds when ablation is required in regions of overlapping moving blood along the periphery of the endoscopic view. Stagnant blood at the center of the endoscopic image represents blood from the target PV that is completely occluded by the balloon. Ablation is avoided in this region due to risk of thrombus formation at any laser energy dose.⁸⁰

The laser ablation catheter technology appears to be equivalent to RF ablation with respect to efficacy and safety in patients with paroxysmal AF. The initial clinical experience with this technology suggests the ability to achieve reliable and lasting PV electrical isolation in patients with highly variable PV shapes and sizes.^{79,80} Unlike other balloon catheters (cryoballoon and high-intensity focused ultrasound [HIFU]), the visually guided laser ablation is unique in that it uses a compliant, variable diameter balloon, thus allowing a single balloon catheter to accommodate multiple PV sizes and shapes. In addition, the endoscope provides real-time direct visualization of the target tissue. Another important feature is the ability to customize the ablation lesion and selectively titrate energy to each part of the circumferential lesion set, similar to point-by-point RF ablation. With other balloon catheters, the operator cannot choose which part of the balloon would deliver ablative energy or adjust the intensity of tissue destruction around the balloon. As a result, the portion of the LA adjacent to the esophagus or phrenic nerve receive the same energy as those areas where deeper lesions are desired.⁸¹

ULTRASOUND ENERGY

Biophysics of Ultrasound Energy

Sound is a propagation of cyclical (oscillatory) displacements of atoms and molecules around their average position in the direction of propagation. When the cyclical events occur at frequencies of more than

20,000 Hz (i.e., higher than those audible to humans), the sound is defined as ultrasound.

Ultrasound beams can be treated in a manner analogous to light beams, including focusing (ultrasonic lens) and minimization of convergence and divergence (collimation). These optical geometric manipulations allow for ultrasound to be directed toward confined distant (deep) tissue volumes. This is a pivotal capability of therapeutic ultrasound.⁸²

Ultrasound energy transmission is subject to attenuation with distance and medium, especially with air. The amount of ultrasound energy transferred to tissue is proportional to the intensity of the wave and the absorption coefficient of the tissue. Because of this property, ultrasound ablation does not require direct contact with the myocardium, in contrast to RF ablation. Ultrasound energy decreases proportionally with the distance ($1/r$), whereas RF ablation electrical conduction decreases with the square of the distance ($1/r^2$). This feature allows ultrasound energy to create deeper and transmural lesions. The duration of application and acoustic power used have a direct relationship with the lesion depth.

Pathophysiology of Lesion Formation by Ultrasound Energy

Tissue injury caused by ultrasound is mediated by thermal and non-thermal mechanisms. Ultrasound waves can propagate through living tissue and fluids without causing any harm to the cells. However, by focusing highly energetic ultrasound waves (HIFU) to a well-defined volume, local heating (achieving a tissue temperature of 65°C to 100°C) occurs and causes rapid tissue destruction by coagulative necrosis. Thermal energy results when the energy transported by an ultrasound beam becomes attenuated as it propagates through viscous (viscoelastic) media, such as human soft tissue. The attenuation partly represents conversion of ultrasound energy into heat.^{82–84}

Nonthermal mechanisms by which HIFU destroys tissue include ultrasonic cavitation, gas body activation, and mechanical stress. Mechanical agitation results from pressure waves (sound waves) propagating in gas-containing tissues as they cyclically expand (explode) and shrink (implode) microbubbles in the tissue (i.e., oscillation and collapse of gas microbubbles), a process known as microcavitation. This process of vibration of cellular structures causes local hyperthermia and mechanical stress by bubble formation because of rapid changes in local pressure, thus leading to cell death.⁸²

Previous studies showed that rapid, focused absorption of HIFU energy in noncardiac tissue produced a steep tissue temperature gradient (2°C to 5°C/s) between the focus and the surrounding tissue, thus allowing for the production of sharply demarcated lesions and reducing collateral damage. However, later studies using HIFU for PV isolation in canine hearts found that HIFU produced a dual temperature profile, probably because of immediate direct acoustic heating and subsequent conductive heating. In addition, the region of direct acoustic heating with HIFU energy *in vivo* was largely predictable from the distance of the target tissue to the HIFU balloon surface; actual tissue temperatures exceeding 50°C (the temperature at which permanent tissue damage is supposed to occur) were focused within a 7-mm width and 7.5-mm depth around the HIFU exit site (significantly larger than the 2- to 3-mm area of resistive heating observed with RF energy). However, the actual distribution of tissue temperatures during lesion generation can be affected by other factors, such as: blood circulation; location of different tissue thicknesses within the atrium, venoatrial junction, or PV; or energy attenuation at various interfaces between the target tissue and the energy source.

HIFU lesion depth increases with longer duration of energy delivery from 15 to 60 seconds, and there is a linear relationship between increasing power and depth of lesions. HIFU applications were found

to achieve transmural lesions and PV electrical isolation. However, although this can translate into increased effectiveness of ablation, it also can potentially lead to collateral damage, namely to the phrenic nerve and esophagus. HIFU ablation can produce damage to the phrenic nerve when it is located within 4 to 7 mm of HIFU exit from its balloon.

Clinical Applications of Ultrasound Energy

HIFU is an attractive alternative energy source. Because it can be focused at specific depths, ultrasound can be advantageous when considering epicardial ablation. The presence of epicardial fat makes the use of standard RF current difficult, both with catheter-based epicardial ablation and minimally invasive surgical ablation. Furthermore, the ability of ultrasound to be collimated through echolucent fluid medium (e.g., water, blood) makes it ideal for a balloon delivery system, which can potentially facilitate circumferential ablation at the PV orifice with a single energy delivery. Another potential advantage of ultrasound is that it does not rely on extensive heating on the vein surface. This can be of value in PV isolation procedures, to help prevent PV stenosis seen with RF ablation. Because HIFU is delivered at the beam convergence site rather than at the tissue surface, successful ablation is less dependent on absolute balloon-tissue contact than other balloon-based technologies. Furthermore, unlike other energy sources, HIFU can be deflected within the balloon to create a wide, focused zone of energy delivery outside the PV orifice, thereby mimicking current wide area circumferential ablative approaches. Currently, no HIFU catheters are available that can be used for linear ablation.

An 8-MHz cylindrical transducer mounted within a saline-filled balloon had been designed for PV isolation. The ablation system (Atrionix, Palo Alto, CA, United States) consists of a 0.035-inch-diameter luminal catheter with a distal balloon (maximum diameter, 2.2 cm) housing a centrally located ultrasound transducer. The system is advanced over a guidewire into the target PV. Tissue surface temperature monitoring is achieved by thermocouples on the balloon and the ultrasound transducer. Despite initial enthusiasm, the long-term report including 33 patients was disappointing, with a long-term cure rate of approximately 30%, although short-term electrical isolation was achieved in all but one of the PVs targeted. Surprisingly, several applications were required to achieve PV isolation. The variability of the PV anatomy was the main culprit for the system failure. In larger PV orifices, it was difficult to achieve adequate heating. The system delivered a narrow band of ultrasound energy radially from a centrally located transducer, and it was at times challenging to place the catheter in all PVs at the proximal portion. Therefore foci at the most proximal lip of a PV may not be ablated successfully.

Later on, a forward-projecting HIFU balloon catheter (ProRhythm, Ronkonkoma, NY, United States) was developed for circumferential PV isolation outside the PV ostia (to limit the risk of PV stenosis). Radially emitted ultrasound is reflected from the back of the balloon, thus resulting in forward projection of ultrasound energy, with a focal point at the balloon-endocardial interface (eFig. 7.6). This system has two noncompliant balloons. A 9-MHz ultrasound crystal is located in the distal balloon filled with contrast and water. The proximal balloon, filled with carbon dioxide, forms a parabolic interface with the distal balloon to reflect the ultrasound energy in the forward direction, by focusing a 360-degree ring (sonicating ring) of ultrasound energy 2 to 6 mm in front of the distal balloon surface. The distal balloon has three sizes—24, 28, or 32 mm in diameter—producing sonicating rings of 20, 25, or 30 mm in diameter. The acoustic power of the system is 45 W for all three balloons, with negligible loss of power in the balloon. The distal balloon is irrigated with contrast and water at 20 mL/min during ablation to keep the balloon cool (lower than 42°C). The

catheter has a central lumen used for insertion of a hexapolar, spiral mapping catheter (ProMap, ProRhythm) for real-time assessment of PV potentials.

Clinical application of this system for PV isolation was shown to be feasible. However, fatal esophageal injury was observed. A study of 28 patients using an esophageal temperature-guided power modulation algorithm to enhance procedural safety demonstrated that acute PV electrical isolation with HIFU ablation could be achieved in only 77% of PVs. Eight percent of PVs could not be isolated with HIFU as a result of excessive esophageal heating or balloon catheter dislodgment. In only 32% of patients, all PVs could be isolated using HIFU ablation only. Although power modulation did not negatively influence short-term success rates of PV electrical isolation, it also did not prevent esophageal temperature from exceeding levels higher than 40.0°C at the end of the ablation. Elevated esophageal temperature prompting cessation of energy delivery occurred in 9% of PVs. Despite use of the safety algorithm and continuous phrenic nerve pacing, transient and persistent phrenic nerve palsy occurred in 14% and 7% of patients, respectively. Even worse, use of the safety algorithm could not prevent occurrence of esophageal thermal damage and lethal atrioesophageal fistula. With mean PV isolation times of less than 15 seconds and a high number of complications, it is evident that the present energy source is too powerful in some patients.⁸⁵

Although PV isolation with HIFU had proven to be successful, it did not meet the safety standards required for treatment of AF, and this led to a halt of its clinical use. The problems of phrenic nerve palsy and atrioesophageal fistula occurrence remain unresolved. Still, the concept of the energy source and mode of energy delivery can be very interesting for future treatment of AF.⁸⁵

MICROWAVE ABLATION

Biophysics of Microwave Energy

Microwaves are the portion of the electromagnetic spectrum between 0.3 and 300 GHz. For the ablation of cardiac arrhythmias, microwave energy has been used at frequencies of 0.915 and 2.450 GHz. Similar to RF, microwave energy produces thermal cell necrosis. However, in contrast to heating by electrical resistance as observed during RF ablation, the mechanism of heating from a high-frequency microwave energy source is dielectrics. Dielectric heating occurs when high-frequency electromagnetic radiation stimulates the oscillation of dipolar molecules (e.g., water molecules) in the surrounding medium at a very high speed, thereby converting electromagnetic energy into kinetic energy. This high-speed vibration causes friction between water molecules within the myocardial wall that results in an increase of myocardial tissue heat. This mode of heating lends microwave ablation the potential for a greater depth of volume heating than RF ablation and should theoretically result in a larger lesion size.⁸⁶

Microwave energy is not absorbed by blood and can propagate through blood, desiccated tissue, or scar. It also can be deposited directly into the myocardial tissue at a distance, regardless of the intervening medium. The microwave energy field generated around the ablation catheter antenna can create myocardial lesions up to 6 to 8 mm in depth without overheating the endocardial surface, a feature that can potentially limit the risk of charring, coagulum formation, and intra-myocardial steam pops. Penetration depth achieved with microwave energy depends on several factors—dielectric properties of the tissue, frequency of the microwave energy, antenna design, and composition and thickness of the cardiac layers.⁸⁶

The effectiveness of microwave ablation depends on the radiating ability of the microwave antenna that directs the electric field and determines the amount transmitted into the myocardium, which is critical

eFig. 7.6 Circumferential Antral Pulmonary Vein (PV) Isolation Using the High-Intensity Focused Ultrasound (HIFU) Balloon Catheter. (A) Schematic representation of the HIFU balloon catheter designed to focus ultrasound energy circumferentially outside the PV (PV antrum). (B) HIFU balloon. (C) Right anterior oblique (RAO) and left anterior oblique (LAO) fluoroscopic views of the angiograms (right) and HIFU balloon positioning (left) in the right superior PV (RSPV). (From Schmidt B, Antz M, Ernst S, et al. Pulmonary vein isolation by high-intensity focused ultrasound: first-in-man study with a steerable balloon catheter. *Heart Rhythm*. 2007;4:575.)

for heating. An end-firing monopolar antenna has been used to produce lesions at depths of 1 cm without disruption of the endocardium in porcine ventricles. The depth of these lesions increased exponentially over time as compared with standard nonirrigated RF energy, which had minimal lesion expansion after 60 seconds of ablation. To concentrate more of the energy distribution near the electrode tip, circularly polarized coil antennas have been developed. Other configurations of the microwave antenna include helical, dipole, and whip designs; these have a large effect on the magnetic field created. However, many of these catheters are still under clinical investigation.⁸⁶

Pathophysiology of Lesion Formation by Microwave Ablation

Microwave energy produces thermal cell necrosis and transmural damage, with foci of coagulation necrosis of myocytes in the central part of the lesion. Hyperthermia (more than 56°C) causes protein denaturation and changes in myocardial cellular EP properties resulting from movement of mobile ions within the aqueous biological medium and altering membrane permeability. The acute myocyte changes include architectural disarray, loss of contractile filaments, and focal interruption of the plasma membrane, which are signs of irreversible injury. In addition, occlusion of the lumen of the small intramyocardial vessels and severe disruption of endothelial and adventitial layers are observed. Carbonization does not occur on tissue surfaces because of the good penetration of microwave energy. Fibrotic tissue eventually replaces the necrotic muscle, which typically becomes sharply demarcated from normal myocardium.

In vitro and in vivo experiments have demonstrated good uniformity in the distribution of the electromagnetic energy throughout the tissue and excellent penetration depth, with no areas of discontinuity over the length of the ablating probe. Energy distribution is maximal near the center of the ablating element, a finding indicating that depth of ablation is relatively deeper at the midpoint of a lesion. There is no indication of edge effect along the ablating tip, which can potentially produce overheating of the tissue surface and induce charring. The temperature at the tissue surface typically remains at less than 100°C over the time required to produce a 6-mm-deep lesion. This is a critical finding because the ability to raise the tissue temperature to 50°C while maintaining it at less than 100°C is paramount to effective and safe hyperthermic ablation.⁸⁷

In addition to the frequency of the microwave energy and length of antenna used, penetration of microwave into the tissue and lesion dimensions is proportional to the power and duration of energy application.⁸⁷

Although microwave ablation in theory should be less likely than RF to induce surface overheating, in vivo studies found that a higher targeted temperature of 90°C resulted in a surface temperature of more than 70°C and was associated with some tissue surface charring when compared with lower temperatures. Therefore the use of the temperature-controlled mode of microwave energy delivery to limit the targeted temperature to 80°C may prevent tissue overheating and reduce the risk of tissue charring. It should be noted that no coagulum formation and no steam pops were observed during any of the microwave ablations performed.⁸⁷

In contrast to RF energy, in which lesion expansion is maximal after 60 seconds, microwave lesion size continues to increase after 300 seconds of energy application. As compared with conventional 4-mm-tip RF ablation, microwave ablation creates a similar lesion depth and width. Lesion length created by a 10-mm antenna is comparable to that created by 8-mm-tip RF ablation. However, because of the lack of physical limitations on the length of the microwave antenna that can be made, microwave ablation may be more advantageous in creating long linear

lesions by using a longer antenna. Nevertheless, a parallel antenna orientation is needed for optimal energy delivery because the growth in lesion sizes is limited beyond the energy field as a result of the finite radial energy distribution of the microwave ablation antenna. Furthermore, the lesion depth created with an 8-mm-tip or saline-irrigated electrode catheter appears to be larger than the lesion depth created by microwave ablation. However, direct comparisons among these different ablation technologies are not available.⁸⁷

Clinical Applications of Microwave Ablation

Microwave ablation can be a promising technique that is potentially capable of treating a wide range of ventricular and supraventricular arrhythmias. The physics of the microwave energy source can be particularly useful for transmural ablation lesions of atrial tissue, as well as the treatment of tachyarrhythmias arising from deep foci of ventricular myocardium.⁸⁶

Microwave can potentially overcome several limitations of RF energy for linear ablation. In contrast to resistive heating produced by RF, microwave generates frictional heat by inducing oscillation of dipoles in a medium such as water. Tissue with higher water content, such as cardiac tissue, allows better energy transfer during the propagation of microwave energy deep into the tissue. Therefore microwave energy is capable of creating deeper lesions, to penetrate scar tissue and to reduce surface heating with less endocardial disruption or coagulation formation. Furthermore, delivery of microwave energy is not limited by electrode size as in RF, and microwave ablation can be applied over a larger surface by modifying antenna size and shape. Another theoretical advantage of microwave energy is that it provides sufficient lesions, independent of contact. However, experimental data have shown that penetration of electromagnetic fields into tissue declines exponentially, and the decline is steep when using frequencies in the microwave range; therefore distance is still an important consideration. Nevertheless, this theoretical advantage can potentially improve the versatility of microwave ablation, especially in areas where muscular ridges and valleys may pose problems for conventional RF ablation.⁸⁶

Currently, microwave ablation has been increasingly used intraoperatively (epicardially or endocardially) during surgical maze procedures. The ability to make microwave antennas into flexible linear applicators and place them parallel to the endocardium by means of clamps has increased the effectiveness of microwave as a tool in open-chest surgery and in minimally invasive surgery.⁸⁸

The development and manufacture of antennae for delivery of microwave energy is technically more complex than for RF electrodes because the efficacy of microwave energy transmission depends mainly on its delivery apparatus. Developments in the catheter-based microwave system may allow the transvenous delivery of microwave energy for endocardial ablation. Only a few case reports have described the successful use of transvenous catheter microwave ablation of the AV junction and CTI. Currently, only one transvenous microwave catheter system (MedWaves, San Diego, CA) is available for investigational use. This system includes a deflectable, 10 Fr catheter with 10-mm or 20-mm helical coil antenna with temperature monitoring, bipolar electrode recording, and a generator delivering microwave at 900 to 930 MHz. Microwave energy is delivered by using a temperature-controlled mode in which the generator automatically adjusts the power output to maintain the targeted temperature of the temperature sensor inside the antenna. For ablation of typical AFL, linear lesions are created with a point-by-point technique with gradual pullback of the microwave catheter across the CTI. Interestingly, microwave causes no perception of pain during ablation of the CTI with energy delivery in the inferior vena cava region.

ELECTROPORATION

DC ablation was investigated in the early 1980s but was abandoned shortly after RF energy emerged as a safer and more effective energy source for catheter ablation. DC ablation was associated with a high rate of serious complications, supposedly related to barotrauma and proarrhythmia. Barotrauma is caused by a high-pressure shock wave resulting from an electrically isolating vapor globe, leading to arcing (spark) and explosion at the catheter tip. Proarrhythmia was thought to result from the nonhomogeneous lesion formation by DC ablation. The effects of this technique were difficult to predict, ranging from no effect on the arrhythmia substrate, to successful ablation, to prolonged myocardial stunning with pulseless electrical activity.⁸⁹

Electroporation is a recent adaptation of low-energy DC catheter ablation. Electroporation uses large electrodes to reduce overall current density, thereby minimizing the risks associated with standard DC catheter ablation.

Tissue damage by electroporation is the result of an electric field-driven reorganization of the lipid structure of the cell membrane. Application of pulsed high-voltage electric field results in penetration of water molecules into the lipid bilayer of the membrane, causing reorientation of the adjacent lipids with their polar head groups toward these water molecules, which leads to the formation of small (nanoscale) pores in the cell membrane. The pores formed in the plasma membrane increase membrane permeability and electrical conductivity and provide a pathway for transport of a wide range of molecules, including DNA, into and out of the cell.

This effect—membrane electroporation—can be either reversible or irreversible. In the range of reversible electroporation, nanopores provide a temporary pathway for transport, but after the electric pulse they gradually reseal, the cells reconstitute their membrane integrity and function, and most cells retain their viability. In the range of irreversible electroporation, higher voltage electric field results in larger nanopores (beyond the reparative capability of the cell), leading to cell death. Other parts of the cell, such as DNA, collagen, or other proteins, are not directly affected by irreversible electroporation. The cutoff between reversible and irreversible electroporation is dependent on the electrical field threshold of the tissue.⁹⁰

The amount of damage caused by electroporation depends on the presence of cell membranes, the applied electrical field, and the electrical resistivity of the target tissue. Therefore tissues can vary in its vulnerability for electroporation, allowing for some degree of tissue specificity for lesion formation.⁹¹

In microbiology, reversible electroporation has been used to transiently increase the permeability of the cell membrane, allowing chemicals, drugs, or new coding DNA to be introduced into the cell (e.g., gene transfection). Irreversible electroporation has been successfully used in the treatment of selected cancers in multiple organs such as the liver, lung, pancreas, kidney, and prostate.

Irreversible electroporation is currently being investigated for catheter ablation of cardiac arrhythmias, and can potentially offer distinct advantages. Unlike other ablation energy sources (such as RF, cryotherapy, microwave, ultrasound, and laser), DC electroporation lesion formation is not thermally mediated.⁹² As a nonthermal therapy, irreversible electroporation is not be impeded by the cold/heat sink effect of local vascular system (which can be of advantage when the ablation target is adjacent to a major coronary artery), is less dependent on perfusion (which is well-suited for epicardial ablation), and is associated with reduced collateral thermal injury. Furthermore, reduced posttreatment inflammation promotes reduced scarring and preservation of the extracellular matrix and major tissue architectural components. In addition, coronary arteries are not or only minimally affected by irreversible

electroporation. The extensive connective tissue around the coronary arteries exhibits a relative reduction in large cell membranes, which makes them relatively invulnerable to irreversible electroporation.^{91,93}

Newer catheter designs (multipolar, large surface area electrodes in a circular arrangement) have been studied in porcine models and shown to produce desirable amounts of ablation on the epicardium without damaging coronary arteries, and in PVs without causing stenosis.⁹⁴

Video 7.1 Cryoballoon Positioning for Pulmonary Vein (PV) Isolation: Contrast PV Angiography. Fluoroscopic images are shown in the right anterior oblique (RAO) and Left anterior oblique (LAO) views during positioning of the cryoballoon at the antrum of the right superior PV (RSPV). Initially, contrast angiography through the balloon catheter reveals distal balloon location within the PV. The balloon is pulled back and maneuvered to optimize antral PV occlusion guided by PV angiography. Similarly, angiography of the right inferior pulmonary vein (RIPV) reveals distal balloon location within the PV. The balloon is pulled back and maneuvered to optimize antral PV occlusion guided by PV angiography. When suboptimal balloon contact with the superior aspect of the RIPV antrum is observed, two maneuvers can be used to facilitate adequate PV occlusion: the “hockey stick technique” and the “pull-down technique.”

Video 7.3 Cryoballoon Positioning for Pulmonary Vein (PV) Isolation: Intracardiac Echocardiography (ICE). ICE imaging is performed with the transducer positioned in the mid right atrium. The cryoballoon is positioned at the antrum of the left superior pulmonary vein (LSPV). Color Doppler imaging reveals persistent flow around the cryoballoon at the inferior aspect of the LSPV, indicating inadequate tissue contact and PV occlusion. Note that flow from the LIPV has to be distinguished from residual flow from the LSPV. LA, Left atrium; LIPV, left inferior pulmonary vein.

Video 7.2 Cryoballoon Pulmonary Vein (PV) Isolation: Contrast Angiography for Assessment of Vein Occlusion. Fluoroscopic images are shown in the right anterior oblique (RAO) projection during positioning of the cryoballoon at the antrum of the left superior pulmonary vein (LSPV). Initially, contrast angiography through the balloon catheter reveals sub-optimal occlusion of the PV antrum by the balloon, as indicated by leak of contrast around the balloon. Repositioning the mapping catheter in a different PV branch helps to change the orientation of the balloon at the PV ostium and achieve PV occlusion on repeat angiography.

Video 7.4 Laser Balloon Pulmonary Vein (PV) Isolation. Fluoroscopic images are shown in the left anterior oblique projection during laser balloon ablation of the left inferior pulmonary vein (LIPV). Initially, contrast angiography of the LIPV is performed via the transseptal sheath. Then, the deflated balloon is advanced into the LIPV and slowly inflated with a mixture of contrast and deuterium dioxide (D_2O). The inflated balloon is manipulated to optimize contact with the antrum of the LIPV. After laser ablation, the balloon catheter is replaced with a circular mapping catheter to confirm electrical isolation of the PV.

ANATOMY AND PHYSIOLOGY OF THE SINUS NODE

Anatomy

The sinus node is a crescent-shaped, subepicardial specialized muscular structure located posterolaterally in the right atrium (RA) free wall. The sinus node lies within the epicardial groove of the sulcus terminalis, at the junction of the anterior trabeculated RA appendage with the posterior smooth-walled venous component (Fig. 8.1). The endocardial aspect of the sulcus terminalis is marked by the crista terminalis. Although the head and proximal body portion of the node usually is located subepicardially beneath the fatty tissues at the junction of the superior vena cava (SVC) and the RA appendage, the remaining nodal body and tail portions penetrate inferiorly and obliquely into the musculature of crista terminalis to end subendocardially almost to the inferior vena cava (IVC). The sinus node is a tadpole-shaped structure with a head, central body, and tail with nodal extensions representing multiple limbs. The head extends toward the interatrial groove, and the tail extends toward the orifice of IVC. In adults the sinus node measures 8 to 22 mm long and 2 to 3 mm wide and thick.¹⁻⁴

Histology

The sinus node appears to be a distributed complex of weakly coupled, heterogeneous cells, including mesh-like nests of densely packed specialized myocytes (the principal pacemaker cell) as well as nonpacemaker cells embedded in a dense supporting connective matrix (see Fig. 8.1).^{1,2,5}

Within the sinus node, pacemaker cells (referred to as P cells because of their relatively pale appearance on electron microscopy) vary by

size, shape, and electrophysiological (EP) properties and may be divided into three major classes: (1) “elongated spindle-shaped cells,” which are spindle shaped but with long cell dimension (extending up to 80 μm in length) and can be multinucleated; (2) “spindle cells,” which have a faintly striated spindle-shaped cell body, similar shape to that of elongated spindle cells, but are shorter in length (extending up to 40 μm) and are predominantly mononucleated; and (3) “spider cells,” which have irregularly shaped branches with blunt ends.^{6,7}

The nodal margins can be discrete, with fibrous separation from the surrounding atrial myocardium, or interdigitating with the atrium though a transitional zone. Commonly, prongs of nodal and transitional cells extend from the nodal central area toward the perinodal region and atrial myocardium. The transitional zone at the node periphery exhibits mosaic features with gradation of cellular structural and membrane EP properties from the primary pacemaker cells to atrial myocardium. Compared with atrial working myocytes, nodal cells are smaller and have fewer myofilaments, poorly developed sarcomeres and sarcoplasmic reticulum, lower cell-to-cell electrical coupling, and higher density of nuclei. A gradient in myofilament content is observed from center to periphery.⁷⁻⁹

Physiology

The sinus node is the dominant pacemaker of the heart. Its pacemaker function is determined by its reduced maximum diastolic membrane potential and steep phase 4 spontaneous depolarization. The molecular mechanisms of pacemaker function of the sinus node are discussed in detail in **Chapters 1 and 3**.

Fig. 8.1 Anatomy of the Sinus Node. Anterior view of the heart in a cadaver that has been dissected to show the course of the right phrenic nerve (RPN) relative to the right atrium (RA). The anticipated location of the sinus node outlined with the dots. The double-headed arrow represents the sectioning plane used for making the cross-sections through the sinus node and the terminal crest (TC) shown in the histological sections. The histological sections in the two upper panels show variations in sizes of the sinus node cross-section and the TC. With this stain (Masson trichrome), the node is recognizable by its fibrous matrix (green) and its artery. The lower panels show variations in nodal location relative to the epicardial and endocardial surfaces and to the superior caval vein (SCV). (From Ho SY, Sánchez-Quintana D. Anatomy and pathology of the sinus node. *J Interv Card Electrophysiol.* 2015;46:3–8, with permission.)

The pacemaker activity is not confined to a single cell in the sinus node; rather, nodal cells function as electrically coupled oscillators that discharge synchronously because of mutual entrainment. It is possible that sinus rhythm results from impulses originating at widely separated sites, with two or three individual wavefronts merging to form a single, widely disseminated wavefront. Mapping of electrograms in and around the node has disclosed a multicentric initiation of activation with irregular propagation to the atrial myocardium.

Current models involve the concept of a “pacemaker hierarchy” within the sinus node, with cells that depolarize at a higher frequency generating faster heart rates located at the superior compartments (head) of the sinus node, whereas slower firing cells are located at the inferior part (tail). The hierarchy mediates heart rate changes (in response to physiological stimuli) via a dynamic craniocaudal shift in the “leading pacemaker” site. For example, sympathetic stimulation shifts the leading pacemaker site superiorly, resulting in an increase in heart rate.³

The sinus node is insulated electrically from the surrounding atrial myocytes, except at a limited number of preferential exit sites that allow transmission of sinus impulses to atrial myocardium. Anatomical insulation (provided by substantial interstitial tissue, fat, and blood vessels) and functional barriers (poor electrical coupling between adjacent cells due to reduced expression of connexins) are critical for protecting the small cluster of pacemaker cells in the sinus node from the hyperpolarizing influence of the surrounding atrial myocardium and enabling “source” nodal cells to overcome the source-sink mismatch and depolarize the much larger surrounding atrial tissue (sink).^{3,6,7,10}

Blood Supply

The blood supply to the sinus node region predominantly comes from a large central artery, the sinus nodal artery, which is a branch of the right coronary artery in 55% to 60% of patients and from the circumflex artery in 40% to 45%. The sinus nodal artery typically passes centrally through the length of the sinus body, and it is disproportionately large, which is considered physiologically important in that its perfusion pressure can affect the sinus rate. Distention of the artery slows the sinus rate, whereas collapse causes an increase in sinus rate.³

Innervation

The sinus node is densely innervated with postganglionic adrenergic and cholinergic nerve terminals (threefold greater density of beta-adrenergic and muscarinic cholinergic receptors than adjacent atrial tissue). Neural and hormonal factors influence both the rate of spontaneous depolarization in pacemaker cells (likely via craniocaudal shift in the principal pacemaker site within the sinus node region) and the point of exit from the sinus node complex to the atrium. These changes often are associated with subtle changes in P wave morphology. The right vagus nerve predominantly affects sinus node function.^{2,5,11}

Enhanced vagal activity can produce sinus bradycardia, sinus arrest, and sinoatrial exit block, whereas increased sympathetic activity can increase the sinus rate and reverse sinus arrest and sinoatrial exit block. Sinus node responses to brief vagal bursts begin after a short latency and dissipate quickly. In contrast, responses to sympathetic stimulation begin and dissipate slowly. The rapid onset and offset of responses to vagal stimulation allow dynamic beat-to-beat vagal modulation of the

heart rate, whereas the slow temporal response to sympathetic stimulation precludes any beat-to-beat regulation by sympathetic activity.^{3,10}

Periodic vagal bursting (as may occur each time a systolic pressure wave arrives at the baroreceptor regions in the aortic and carotid sinuses) induces phasic changes in the sinus cycle length (CL) and can entrain the sinus node to discharge faster or slower at periods identical to those of the vagal burst. Because the peak vagal effects on sinus rate and atrioventricular node (AVN) conduction occur at different times in the cardiac cycle, a brief vagal burst can slow the sinus rate without affecting AVN conduction or can prolong AVN conduction time and not slow the sinus rate.

PATHOPHYSIOLOGY OF SINUS NODE DYSFUNCTION

Sinus node dysfunction (SND) refers to a wide range of abnormalities involving sinus node and atrial impulse generation and propagation, leading to the inability of the sinus node to generate heart rates that are appropriate for the physiological needs. Causes of SND can be classified as intrinsic (secondary to a pathological condition involving the sinus node proper, [Box 8.1](#)) or extrinsic (caused by depression of sinus node function by external factors such as drugs or autonomic influences, [Box 8.2](#)).

Not only automaticity of the individual nodal cells but also architectural factors at the tissue level are essential for normal pacemaking function. Defects in sinus node architecture can disrupt the normal source-sink balance, leading to SND. Structural changes (e.g., sinus nodal cell loss and fibrosis) and alterations in the normal gradient of EP properties in the sinus node complex likely underlie slowing of pacemaking with normal aging and cardiovascular disease (e.g., atrial fibrillation [AF], heart failure). Furthermore, autonomic modulation, adenosine, ischemia, and structural remodeling can potentially lead not only to depression of sinus pacemaker function but also to complete block of conduction through all nodal conduction pathways.^{6,12–14}

Intrinsic Sinus Node Dysfunction

Degenerative Diseases

SND is generally a disease of aging, and idiopathic degenerative disease is probably the most common cause of intrinsic SND. Aging-related

progressive fibrosis with cell loss and degeneration (structural remodeling), as well as EP remodeling of the sinus node (e.g., during AF), are important factors in the pathophysiology of SND. These degenerative changes are typically more diffuse, affecting surrounding atrial tissue (atrial remodeling or “atriopathy”), as well as other parts of the conduction system. The frequent lack of an effective escape rhythm in patients with SND and the long asystolic pauses are likely a manifestation of the diffuse nature of the conduction system disease.^{5,9,15}

Ischemic Heart Disease

Coronary artery disease is very common among SND patients. Although this can be coincidental, because both diseases tend to occur in older individuals, ischemic heart disease is thought to be responsible for as much as one-third of chronic SND. In addition, SND (sinus bradycardia or sinus arrest) is observed in up to 15% to 25% of patients with acute myocardial infarction (MI), most commonly in inferior and posterior infarctions.

SND after an acute MI is usually a transient phenomenon, most commonly related to increased vagal tone, and is generally associated with other signs of vagotonia, such as atrioventricular (AV) conduction delay, and is responsive to atropine and catecholamine stimulation. Possible mechanisms include neurological reflexes (Bezold-Jarisch reflex), coronary chemoreflexes (vagally mediated), humoral reflexes (enzymes, adenosine, potassium [K⁺]), and oxygen-conserving reflex (“diving” reflex). Pain and the use of vagotonic medications, such as morphine, can potentiate vagal tone and exacerbate SND. However, infarction or ischemia of the sinus node or the surrounding atrium (e.g., secondary to proximal occlusion of the right or the circumflex coronary artery) can also cause SND, which can be more persistent.⁹

BOX 8.1 Causes of Intrinsic Sinus Node Dysfunction

Idiopathic degenerative disorder (most common)
Ischemic heart disease
Genetic defects: mutations in *SCN5A*, *HCN4*, *GJA5*, *ANK2*, and *EMD* genes
Atrial tachyarrhythmias
Hypertensive heart disease
Cardiomyopathy
Congenital heart disease: sinus venosus atrial septal defect, left atrial isomerism
Surgical trauma: Mustard, Senning, Glenn, and Fontan procedures
Cardiac transplant
Inflammatory diseases: rheumatic fever, pericarditis, myocarditis
Infectious causes: Lyme disease, legionella, Q fever, typhoid, psittacosis, malaria, leptospirosis, Chagas disease
Collagen vascular disease: systemic lupus, scleroderma
Infiltrative diseases: amyloidosis, sarcoidosis, hemochromatosis, tumors
Neuromuscular disorders: Friedreich ataxia, myotonic dystrophy, Emery-Dreifuss muscular dystrophy

BOX 8.2 Causes of Extrinsic Sinus Node Dysfunction

Drugs

Antiarrhythmic agents
Class IA: quinidine, procainamide
Class IC: propafenone, flecainide
Class II: beta blockers
Class III: sotalol, amiodarone, dronedarone
Class IV: diltiazem, verapamil
Ivabradine
Digitalis
Sympatholytic antihypertensive agents: clonidine, reserpine, methyldopa
Parasympathomimetic agents: acetylcholine, carbachol, acetylcholinesterase inhibitors
Opioids: morphine
Antipsychotic agents: lithium, phenothiazines, amitriptyline
Chemotherapeutic agents: thalidomide, paclitaxel
Miscellaneous: cimetidine, phenytoin

Autonomic influences

Excessive vagal tone
Neurocardiogenic syncope (cardioinhibitory)
Carotid sinus hypersensitivity (cardioinhibitory)
Well-trained athletes

Hypothermia

Hyperkalemia
Increased intracranial pressure (the Cushing response)
Hypoxemia
Hypercapnia
Sleep apnea
Hypothyroidism

Atrial Arrhythmias

Atrial tachyarrhythmias can precipitate SND, likely secondary to sinus node remodeling. Although early studies implicated anatomical structural abnormalities in the sinus node, which suggested a fixed SND substrate, more recent evidence has implicated a functional, and potentially reversible, component involving remodeling of sinus node ion channel expression and function.¹¹ This finding is supported clinically by the observation that successful catheter ablation of AF and atrial flutter (AFL) can be followed by significant improvements in sinus node function. In particular, downregulation of the funny current (I_f) and malfunction of the calcium (Ca^{2+}) clock (characterized by reduced sarcoplasmic reticulum Ca^{2+} release and downregulated ryanodine receptors in the sinus node) seem to account largely for tachycardia-induced remodeling of sinus node.¹⁶ The remodeled atria are associated with more caudal activation of the sinus node complex, slower conduction time along preferential pathways, and only modest shifts within the functional pacemaker complex.^{17,18} Endogenous adenosine recently has been implicated in the pathophysiology of SND following termination of atrial tachyarrhythmias.^{5,19}

On the other hand, SND has been associated with an increased propensity for atrial tachyarrhythmias, AF in particular.²⁰ The mechanism leading to AF in patients with SND is unlikely to be bradycardia-dependent because AF was found to develop despite pacing in these patients. Importantly, patients with SND appear to have more widespread atrial changes beyond the sinus node, a finding indicating atrial myopathy with fibrosis and scar formation, as evidenced by increased atrial refractoriness, prolonged P wave duration, conduction slowing, electrogram fractionation, and regions of low voltage and scar.⁵ Furthermore, abnormal atrial electromechanical properties, chronic atrial stretch, and neurohormonal activation are likely contributors to SND and its related atrial myopathy. Atrial and sinus node remodeling in heart failure, hypertension, and aging have shown caudal shift of the pacemaker complex with loss of normal multicentric pattern of activation. Similar and often more severe atrial and sinus node remodeling has been observed in patients with intermittent atrial tachyarrhythmias. The diffuse atrial myopathy potentially underlies the increased propensity to both SND and atrial arrhythmias.^{10,21–25}

Familial Sinus Node Dysfunction

Genetic defects in ion channels and structural proteins have been shown to contribute to SND, many of which also exhibit an increased propensity to AF. Mutations in the *SCN5A* gene (which encodes the alpha subunit of the cardiac sodium [Na^+] channel [I_{Na}]), have been linked to sick sinus syndrome, manifesting as sinus bradycardia, sinus arrest, sinoatrial block, or a combination of these conditions, which can progress to atrial inexcitability (atrial standstill). Loss-of-function *SCN5A* mutations result in reduced peak I_{Na} density, hyperpolarizing shifts in the voltage dependence of steady-state channel availability, and slow recovery from inactivation. These effects likely cause reduced automaticity, decreased excitability, and conduction slowing or block of impulses generated in the sinus node to the surrounding atrial tissue. SND can also manifest concomitantly with other phenotypes that are linked to *SCN5A* loss-of-function mutations such as Brugada syndrome and progressive cardiac conduction disorders (Lev-Lenègre disease).^{8,9,26–29}

Heterozygous mutations in the *HCN4* gene (which encodes the protein that contributes to formation of I_f channels) have been identified in individuals with sinus bradycardia and chronotropic incompetence. Severe bradycardia, QT prolongation, and torsades de pointes have been described in another family. *HCN* mutations slow channel activation kinetics or, when located in cyclic nucleotide-binding domains, abolish sensitivity of HCN channels to cyclic adenosine monophosphate, thus reducing I_f and the rate of diastolic depolarization.^{8,30}

Several other mutations have been associated with familial forms of SND, including mutations in the *ANK2* gene (which encodes for ankyrin, which links the integral membrane proteins to the underlying cytoskeleton), the *MYH6* gene (which encodes for atrial myosin heavy chain), and the *EMD* gene (which encodes the nuclear membrane protein emerin). Mutations in the *GJA5* gene (which encodes for connexin 40, a gap junction protein), have been associated with individuals with atrial standstill and AF. In addition, mutations in the calsequestrin gene (*CASQ2*), which is involved in Ca^{2+} handling and is associated with catecholaminergic polymorphic ventricular tachycardia, have been linked to SND.^{8,26,27,31}

Congenital Heart Disease

Congenital heart disease, such as sinus venosus atrial septal defects, can be associated with SND, even though no surgery has been performed. Heterotaxy syndromes, particularly left atrial (LA) isomerism, can be associated with congenital absence of the sinus node.^{28,32}

A more common cause of SND in patients with congenital heart disease is sinus node injury caused by corrective cardiac surgery. Most commonly associated with this complication is the Mustard, Senning, Glenn, and Fontan operations, as well as repair of atrial septal defects, especially of the sinus venosus type. Surgical incisions, suture lines, and cannulation of the SVC can result in direct damage to the sinus node, its blood supply, or neural inputs.³² In addition, SND may develop as a consequence of longstanding hemodynamic perturbations or the atrial arrhythmias frequently observed in this patient population.

Other Causes

Cardiomyopathy and longstanding hypertension can result in SND. Orthotopic cardiac transplantation with atrial-atrial anastomosis is associated with a high incidence of SND in the donor heart (likely because of sinus nodal artery damage); this is far less likely with a caval-caval anastomosis. Musculoskeletal disorders such as myotonic dystrophy or Friedreich ataxia are rare causes of SND. Other causes of SND include a variety of infiltrative, infectious, and inflammatory disorders (see Box 8.1).

Extrinsic Sinus Node Dysfunction

In the absence of structural abnormalities, the predominant causes of SND are drug effects and autonomic influences (see Box 8.2).

Drugs

Drugs can alter sinus node function by direct pharmacological effects on nodal tissue or indirectly by neurally mediated effects. Drugs known to depress sinus node function include beta-blockers, calcium channel blockers (verapamil and diltiazem), digoxin, sympatholytic antihypertensive agents (e.g., clonidine), and antiarrhythmic agents.

Autonomic Influences

SND can sometimes result from excessive vagal tone in individuals without intrinsic sinus node disease. Hypervagotonia can be seen in hypersensitive carotid sinus syndrome and neurocardiogenic syncope.³³ Surges in vagal tone also can occur during Valsalva maneuvers, endotracheal intubation, vomiting, and coughing. Sinus slowing in this setting is characteristically paroxysmal and may be associated with evidence of AV conduction delay, secondary to effects of the enhanced vagal tone on both the sinus node and AVN.

Significant sinus bradycardia is very common in highly conditioned athletes and is usually correlated to type and intensity of training. Respiratory sinus arrhythmia, wandering pacemaker, junctional bradycardia, first-degree AV block, and Wenckebach second-degree AV block are also more common in this population. These changes, at least

in the initial stages, have been attributed to increased vagal tone. However, over time, endurance training does lead to intrinsic changes in the sinus node and the cardiac conduction system potentially related to dilatation and hypertrophy of the athlete's heart. Deconditioning of athletes can sometimes help to prevent symptomatic bradyarrhythmias; however, it is not uncommon that slow heart rates persist for many years after training has stopped.³⁴

Other Causes

Obstructive sleep apnea can be associated with significant sinus bradycardia and long sinus pauses during apneic episodes. Less common extrinsic causes of SND include electrolyte abnormalities such as hyperkalemia, hypothermia, increased intracranial pressure (the Cushing response), hypoxia, hypercapnia, hypothyroidism, and obstructive jaundice.

CLINICAL PRESENTATION

Patients with SND often are asymptomatic or have symptoms that are mild and nonspecific, and the intermittent nature of these symptoms makes documentation of the associated arrhythmia difficult at times. In addition, because most patients with SND are elderly, symptoms of the disease can erroneously be attributed to the aging process or other comorbidities.

Symptoms of SND include paroxysmal dizziness, presyncope, or syncope, which are predominantly related to prolonged sinus pauses. Episodes of syncope are often unheralded and can manifest in older patients as repeated falls. The highest incidence of syncope associated with SND probably occurs in patients with tachycardia-bradycardia syndrome, in whom syncope typically occurs secondary to a long sinus pause following cessation of the supraventricular tachyarrhythmia (usually AF). Occasionally, a stroke can be the first manifestation of SND in patients presenting with paroxysmal AF and thromboembolism.

Patients with sinus bradycardia or chronotropic incompetence often present with decreased exercise capacity or fatigue. Chronotropic incompetence is estimated to be present in 20% to 60% of patients with SND. Other symptoms include irritability, nocturnal wakefulness, memory loss, lightheadedness, and lethargy. More subtle symptoms include mild digestive disturbances, periodic oliguria or edema, and mild intermittent dyspnea. In addition, symptoms caused by the worsening of conditions such as congestive heart failure and angina pectoris can be precipitated by SND.

EPIDEMIOLOGY AND NATURAL HISTORY

SND is largely a disease of the elderly, and its incidence increases exponentially with age. Most SND patients are in their seventh or eighth decade of life and have frequent comorbid diseases. SND in young patients is often related to underlying heart disease. Although the exact incidence of SND is difficult to determine, a recent report estimated the incidence of SND at 0.8 per 1000 person-years. SND likely accounts for 50% or more of permanent pacemaker placements in the United States. With the aging population, it is projected that the annual incidence of SND cases in the United States will increase from 78,000 in 2012 to 172,000 in 2060 (Fig. 8.2). The most significant risk factor for SND is advancing age. Other risk factors include greater body mass index, longer QRS duration, hypertension, right bundle branch block, and cardiovascular disease. Blacks carry a 41% lower risk of SND than whites. Men and women appear equally affected.³⁵

The natural history of SND can be variable, but slow progression (over 10 to 30 years) is expected. The prognosis largely depends on the type of SND and the presence and severity of the underlying heart disease. SND does not appear to affect survival whether untreated or

Fig. 8.2 Incidence of Sick Sinus Syndrome. Estimated number of incident sick sinus syndrome (SSS) cases per year, overall and by age group in the United States, 2012 to 2060. (From Jensen PN, Gronroos NN, Chen LY, et al. Incidence of and risk factors for sick sinus syndrome in the general population. *J Am Coll Cardiol*. 2014;64:531–538, with permission.)

treated with pacemaker therapy. The incidence of sudden death is extremely low; mortality in patients with SND is primarily determined by underlying heart disease. The worst prognosis is associated with the tachycardia-bradycardia syndrome (mostly because of the risk for thromboembolic complications), whereas sinus bradycardia is much more benign.

Up to 50% of SND patients experience episodes of AF over a lifetime. The incidence of new-onset AF in patients with SND is approximately 5.2% per year. Atrial-based pacing (AAI or DDD) in SND patients is associated with a 20% reduction in risk of AF and stroke as compared with single-chamber ventricular pacing.

The incidence of advanced AV conduction system disease in patients with SND is relatively low (5% to 10%), and, when present, its progression is slow. At the time of diagnosis of SND, approximately 17% of the patients have some degree of AV conduction system disease (PR interval longer than 240 milliseconds, BBB, HV interval prolongation, AV Wenckebach rate less than 120 beats/min, or second- or third-degree AV block). New AV conduction abnormalities develop at a rate of approximately 7% per year in patients with baseline BBB or bifascicular block but much less frequently (0.6% to 1.8% per year) in those without any evidence of AV or intraventricular conduction abnormalities. The incidence of advanced AV block during long-term follow-up is low (approximately 1% per year).³⁶

DIAGNOSTIC EVALUATION

In general, the noninvasive methods of electrocardiogram (ECG) monitoring, exercise testing, and autonomic testing are used first. However, if symptoms are infrequent and noninvasive evaluation is unrevealing, invasive EP testing can be considered.

Electrocardiogram and Ambulatory Monitoring

A 12-lead ECG needs to be obtained in symptomatic patients. However, the diagnosis of SND as the cause of the symptoms is rarely made from the ECG. In patients with frequent symptoms, 24- or 48-hour ambulatory Holter monitoring can be useful. Cardiac event monitoring or implantable loop recorders may be necessary in patients with less frequent symptoms. Documentation of symptoms in a diary by the patient while wearing the cardiac monitor is essential for correlation of symptoms

with the heart rhythm at the time. In some cases, ambulatory monitoring can exclude SND as the cause of symptoms if normal sinus rhythm (NSR) is documented at the time of symptom occurrence. In contrast, recorded sinus pauses may not be associated with symptoms.

Autonomic Modulation

An abnormal response to carotid sinus massage (pause longer than 3 seconds) can indicate SND, but this response can also occur in asymptomatic older individuals. Heart rate response to the Valsalva maneuver (normally decreased) or upright tilt (normally increased) can also be used to verify that the autonomic nervous system itself is intact. Complete pharmacological autonomic blockade is used to determine the intrinsic heart rate (see later).

Exercise Testing

Exercise testing to assess chronotropic incompetence is of value in patients with exertional symptoms (see later).

Electrophysiological Testing

In the majority of patients, noninvasive testing is adequate in establishing the diagnosis of SND and guiding subsequent therapy. However, invasive EP testing can be of value in symptomatic patients in whom SND is suspected but cannot be documented in association with symptoms. In addition to assessing the function of the sinus node, EP testing can be useful in evaluating other potential causes for symptoms of syncope and palpitations (e.g., AV block, supraventricular tachycardia, and ventricular tachycardia).

ELECTROCARDIOGRAPHIC FEATURES

Sinus Bradycardia

Sinus bradycardia (less than 60 beats/min) is considered abnormal when it is persistent, unexplained, and inappropriate for physiological circumstances. Sinus bradycardia slower than 40 beats/min (not associated with sleep or physical conditioning) is generally considered abnormal.

Sinus Arrest

The terms *sinus arrest* and *sinus pause* are often used interchangeably; sinus arrest is a result of total cessation of impulse formation within the sinus node. The pause is not an exact multiple of the preceding P-P interval but is random in duration (Fig. 8.3). Although asymptomatic pauses of 2 to 3 seconds can be seen in up to 11% of normal individuals and in one-third of trained athletes (especially during sleep), pauses longer than 3 seconds are rare in normal individuals and may or may not be associated with symptoms, but they are usually caused by underlying SND.

Sinoatrial Exit Block

Sinoatrial exit block results when a normally generated sinus impulse fails to conduct to the atria because of delay in conduction or block

within the sinus node itself or perinodal tissue. Sinoatrial exit block produces a pause that is eventually terminated by a delayed sinus beat or an atrial or junctional escape beat. In theory, sinoatrial exit block can be distinguished from sinus arrest because the exit block pause is an exact multiple of the baseline P-P interval. However, sinus arrhythmia causing normal beat-to-beat variations in the sinus rate often makes the distinction impossible. Establishing the diagnosis of sinoatrial exit block versus sinus arrest is often of academic interest only.

Sinoatrial exit block is classified into three types, analogous to those of AV block: first-degree, second-degree, and third-degree exit block. First-degree sinoatrial exit block is caused by abnormal prolongation of the sinoatrial conduction time (SACT). It occurs every time a sinus impulse reaches the atrium, but it is conducted with a delay at a fixed interval. This type of sinoatrial exit block is concealed on the surface ECG and can be diagnosed only by direct sinus node recording or indirect measurement of SACT during an EP study.

Second-degree sinoatrial exit block is marked by intermittent failure of the sinus impulse to exit the sinus node. Type I block is viewed as Wenckebach periodicity of the P wave on the surface ECG, and it manifests as progressive delay in conduction of the sinus-generated impulse through the sinus node to the atrium, finally resulting in a nonconducted sinus impulse and absence of a P wave on the surface ECG. Because the sinus discharge is a silent event on the surface ECG, this arrhythmia can be inferred only, because of a missing P wave and the signs of Wenckebach periodicity seen with this type of arrhythmia. The increment in delay in impulse conduction through the sinus node tissue is progressively less; thus the P-P intervals become progressively shorter until a P wave fails to occur. The pauses associated with this type of sinoatrial exit block are less than twice the shortest sinus cycle.

Type II block manifests as an abrupt absence of one or more P waves because of failure of the sinus impulse to exit the sinus node, without previous progressive prolongation of SACT (and without progressive shortening of the P-P intervals). Sometimes, two or more consecutive sinus impulses are blocked within the sinus node, thus creating considerably long pauses. The sinus pause should be an exact multiple of the immediately preceding P-P interval. However, normal variations in the sinus rate caused by sinus arrhythmia can obscure this measurement.

Third-degree or complete sinoatrial exit block manifests as absence of sinus P waves, with long pauses resulting in lower pacemaker escape rhythm. This type of block is impossible to distinguish from sinus arrest with certainty without invasive sinus node recordings.

Chronotropic Incompetence

The term *chronotropic incompetence* is used to denote an inadequate heart rate response to increases in metabolic demands. Although the resting heart rate can be normal, patients with chronic incompetence are unable to increase their heart rate during exercise or may have unpredictable fluctuations in the heart rate during activity. Some patients can initially experience a normal increase in the heart rate with exercise, which then plateaus or decreases inappropriately.

Fig. 8.3 Sinus Pause. Sinus pause is shown in two monitor leads. Although the sinus rate is slightly irregular, the pause significantly exceeds any two P-P intervals (excluding sinus exit block). *MCL*, Modified chest lead.

Fig. 8.4 Chronotropic Incompetence. (A) A 24-hour Holter recording in a normal subject showing normal sinus rate diurnal variation and response to activity. (B) A 24-hour Holter recording in a different patient with chronotropic incompetence and activity intolerance. Note the blunted response of the sinus rate to activity during waking hours and the slow average heart rate. *BPM*, Beats per minute.

On 24-hour ambulatory Holter monitoring, chronotropic incompetence commonly manifests as a monotonic daily heart rate profile in an ambulatory patient (Fig. 8.4). In addition, treadmill exercise testing can be of substantial value in assessing the chronotropic response (“competence”) to increases in physical activity in patients with sinus bradycardia who are suspected of having SND. Although the definition of chronotropic incompetence is not agreed on, it is reasonable to designate it as a blunted heart rate response to exercise manifesting as a less than normal increase in the sinus rate at each stage of exercise, with a plateau at less than 70% to 80% of the age-predicted maximum heart rate ($220 - \text{age}$) at peak exercise (having completed at least two stages of exercise testing using a modified Bruce protocol) or an inability to achieve a sinus rate of 100 to 120 beats/min at maximum effort. Irregular (and nonreproducible) increases, and even decreases, in the sinus rate during exercise, can also occur but are rare. Other patients with SND can achieve an appropriate peak heart rate during exercise but may have slow sinus rate acceleration in the initial stage or rapid deceleration of heart rate in the recovery stage.

Tachycardia-Bradycardia Syndrome

Tachycardia-bradycardia syndrome, frequently referred to as sick sinus syndrome, is a common manifestation of SND, and it refers to the

presence of intermittent sinus or junctional bradycardia alternating with atrial tachyarrhythmias (Fig. 8.5). The atrial tachyarrhythmia is most commonly paroxysmal AF, but AT, AFL, and occasionally atrio-ventricular nodal reentry tachycardia or AVRT can also occur.

Apart from underlying sinus bradycardia of varying severity, these patients often experience prolonged sinus arrest and asystole on termination of the atrial tachyarrhythmia, resulting from overdrive suppression of the sinus node and secondary pacemakers by the tachycardia. Long sinus pauses that occur following electrical cardioversion of AF constitute another manifestation of SND.

Therapeutic strategies to control the tachyarrhythmias often cause SND and result in the need for pacemaker therapy (Fig. 8.6). On the other hand, long sinus pauses occurring following tachycardia episodes can be reversible in some patients once the tachyarrhythmia is eliminated, thus obviating the need for pacing.

Atrial Fibrillation With Slow Ventricular Response

Persistent AF with a slow ventricular response in the absence of AVN blocking drugs is often present in patients with SND. These patients can demonstrate very slow ventricular rates at rest or during sleep and occasionally have long ventricular pauses. Occasionally, they can develop complete AV block with a junctional or ventricular escape rhythm.

Fig. 8.5 Tachycardia-Bradycardia Syndrome. Two surface electrocardiogram leads showing atrial fibrillation that spontaneously terminates followed by a 5.9-second pause before sinus rhythm resumes. The patient became lightheaded during this period.

Fig. 8.6 Sinus Node Dysfunction and Atrial Fibrillation. A 24-hour Holter heart rate trend showing slow sinus bradycardia (average sinus rate <50 beats/min) alternating with rapid ventricular rates (averaging >120 beats/min) during a sustained episode of atrial fibrillation. Pacing was required in this patient to prevent symptomatic bradycardia and allow the use of drug therapy to control the tachycardia.

They can also conduct rapidly and develop symptoms caused by tachycardia during exercise. In some cases, cardioversion results in a long sinus pause or junctional escape rhythm before the appearance of sinus rhythm. Although a combination of sinus node and AV conduction disease can be present in many cases, examples of rapid ventricular responses during atrial tachyarrhythmias are frequently found.

Carotid Sinus Hypersensitivity

An abnormal response to carotid sinus massage (pause longer than 3 seconds) can indicate SND, but this response can also occur in asymptomatic older individuals (eFig. 8.1).³³

Atrial Standstill

Atrial standstill is a rare clinical syndrome in which there is no spontaneous atrial activity and the atria cannot be electrically stimulated. The surface ECG usually reveals junctional bradycardia without atrial

activity (eFig. 8.2). The atria are generally fibrotic and without any functional myocardium. Lack of mechanical atrial contraction poses a high risk for thromboembolism in these patients.

Sinus Arrhythmia

Sinus arrhythmia is present when the P wave morphology is normal and consistent and the P-P intervals vary by more than 120 milliseconds (or by more than 10% of the shortest P-P interval). The PR interval generally does not vary significantly (because of the consistent site of impulse generation, i.e., the sinus node).

Respiratory sinus arrhythmia is mediated by atrial stretch receptors, which respond to increased and decreased venous return during inspiration and expiration by speeding or slowing sinus rate, respectively. Respiratory sinus arrhythmia is not an abnormal rhythm and is most commonly seen in young healthy subjects, especially those with slower heart rates or with enhanced vagal tone.³⁴

eFig. 8.1 Carotid Sinus Hypersensitivity. Two surface electrocardiogram leads are shown during carotid sinus pressure, as indicated. The PR interval is prolonged, followed by a 7.5-second sinus pause ended by a P wave and probable junctional escape complex. The patient was nearly syncopal during this period.

eFig. 8.2 Atrial Standstill. Surface electrocardiogram showing sinus arrest with escape junctional rhythm in a patient with atrial standstill.

Fig. 8.7 Ventriculophasic Sinus Arrhythmia. Surface electrocardiogram during sinus rhythm with second-degree 2:1 atrioventricular block. Consecutive sinus P waves enclosing a QRS occur at shorter intervals than that of consecutive P waves without a QRS in between (ventriculophasic arrhythmia).

Nonrespiratory sinus arrhythmia, in which phasic changes in sinus rate are not related to the respiratory cycle, can be accentuated by the use of vagal agents such as digitalis and morphine; its mechanism is unknown. Patients with nonrespiratory sinus arrhythmia are likely to be older and to have underlying cardiac disease, although the arrhythmia itself is not a marker for structural heart disease. None of the sinus arrhythmias (respiratory or nonrespiratory) indicate SND. In addition, respiratory variation in the sinus P wave contour can be seen in the inferior leads and should not be confused with wandering atrial pacemaker, which is unrelated to breathing and therefore is not phasic.

Ventriculophasic sinus arrhythmia is an unusual rhythm that occurs when sinus rhythm and high-grade or complete AV block coexist; it is characterized by shorter P-P intervals when they enclose QRS complexes and longer P-P intervals when no QRS complexes are enclosed (Fig. 8.7). The mechanism is uncertain but may be related to the effects of the mechanical ventricular systole itself: ventricular contraction increases the blood supply to the sinus node, thereby transiently increasing its firing rate. Ventriculophasic sinus arrhythmia is not a pathological arrhythmia and should not be confused with premature atrial complexes or sinoatrial block.

Wandering Atrial Pacemaker

Wandering atrial pacemaker is characterized by multiple P waves of varying morphology with a relatively normal or slow rate, caused by shifting of the dominant pacemaker focus between the sinus node and latent pacemakers in other atrial and AV junctional sites (eFig. 8.3). The shift in pacemaker focus occurs gradually, over the course of several beats, so that only one pacemaker at a time controls the rhythm. In addition to a change in P wave morphology, the shift in pacemaker focus is usually associated with different PR intervals (depending on its proximity to the AVN) and R-R intervals. By definition, wandering atrial pacemaker has to have at least three distinctly different P wave morphologies and a ventricular rate of less than 100 beats/min. Wandering pacemaker is a normal phenomenon, usually caused by varying

vagal tone, and can be observed in young healthy subjects and athletes, especially during sleep or with enhanced vagal tone, but also in patients with SND. Wandering pacemaker is rarely symptomatic.

ELECTROPHYSIOLOGICAL TESTING

Role of Electrophysiological Testing

The diagnosis of SND usually can be made based on clinical and ECG findings, which are typically adequate for deciding subsequent treatment. After symptoms and SND are correlated with ECG findings, further documentation by invasive studies is not required. Similarly, asymptomatic patients with evidence of SND need not be tested because no therapy is indicated. However, EP testing can be important to assess sinus node function in patients who have had symptoms compatible with SND and in whom no documentation of the arrhythmia responsible for these symptoms has been obtained by prolonged monitoring. In these cases, EP testing can yield information that can be used to guide appropriate therapy. The most useful measures of the overall sinus node function are a combination of the responses to atropine and exercise and the sinus node recovery time (SNRT).³⁷

Sinus Node Recovery Time

The sinus node is the archetype of an automatic focus. Automatic rhythms are characterized by spontaneous depolarization, overdrive suppression, and post-overdrive warm-up (i.e., gradual return to baseline CL). SNRT is the interval between the end of a period of overdrive pacing and the return of sinus node function, manifest on the surface ECG by a postpacing sinus P wave. Clinically, SNRT is used to test sinus node automaticity.³⁷

Technique

Pacing site. Pacing is performed in the high RA at a site near the sinus node, to decrease the conduction time to and from the sinus node.

eFig. 8.3 Wandering Atrial Pacemaker. Surface electrocardiogram showing wandering atrial pacemaker with multiple P waves of varying morphology with a relatively normal rate.

Pacing cycle length. SNRT is preferably measured after pacing at multiple CLs. Pacing is started at a CL just shorter than the sinus CL. After a 1-minute rest, pacing is repeated at progressively shorter CLs (with 50- to 100-millisecond decrements) down to a pacing cycle length (PCL) of 300 milliseconds.

Pacing duration. Pacing is continued for 30 or 60 seconds at a time. Although pacing durations beyond 15 seconds usually have little effect on the SNRT in healthy subjects, patients with SND can manifest marked suppression after longer pacing durations. It is also preferable to perform pacing at each PCL for different durations (30, 60, or 120 seconds), to ensure that sinus entrance block has not obscured the true SNRT.

Measurements

Several intervals have been used as a measure of SNRT.³⁷

Sinus node recovery time. SNRT is the longest pause from the last paced beat to the first sinus return beat at a particular pacing CL. Normally, SNRT is less than 1500 milliseconds, with a scatter on multiple tests of less than 250 milliseconds (Fig. 8.8). SNRT tends to be shorter with shorter baseline sinus CLs, and therefore various corrections have been introduced.

Corrected SNRT. Corrected SNRT equals SNRT minus the baseline sinus CL. Normal values of corrected SNRT have been reported from 350 to 550 milliseconds, with 500 milliseconds most commonly used (see Fig. 8.8). However, the use of corrections at slow sinus rates can produce odd results. For example, in a patient with symptomatic bradycardia at a 1500-millisecond CL and an SNRT of 2000 milliseconds, the corrected SNRT is 500 milliseconds. For cases of severe bradycardia, an abnormal uncorrected SNRT of 2000 milliseconds is more accurate; in fact, one does not need SNRT to make the clinical diagnosis.

Maximum SNRT. Maximum SNRT is the longest pause from the last paced beat to the first sinus return beat at any pacing CL.

Ratio of SNRT to sinus CL. The ratio of $[(\text{SNRT}/\text{sinus CL}) \times 100\%]$ is lower than 160% in normal subjects.

Total recovery time. On cessation of atrial pacing, the pattern of subsequent beats returning to the basic sinus CL should be analyzed. Various patterns exist. Total recovery time equals the time to return to basic sinus CL (normal total recovery time is less than 5 seconds, usually by the fourth to sixth recovery beat).

Secondary pauses. Normally, following cessation of overdrive pacing, a gradual shortening of the sinus CL is observed until the baseline sinus CL is reached, typically within a few beats. Limited oscillations of

recovery CLs before full recovery can be observed, especially at faster pacing rates. Secondary pauses are identified when there is an initial shortening of the sinus CL after the SNRT, followed by an unexpected lengthening of the CL (see Fig. 8.8). Sudden and marked secondary pauses occurring during sinus recovery are abnormal. Sinoatrial exit block of variable duration is the primary mechanism of prolonged pauses, with a lesser component of depression of automaticity. Both may, and often do, coexist. However, secondary pauses can be a normal reflex following hypotension induced by pacing at rapid rates or in response to pressure overshoot in the first recovery beat resulting from the prolonged filling time. Because these secondary pauses represent SND and because they occur more frequently following rapid atrial pacing, overdrive pacing should be performed at rates up to 200 beats/min.

Limitations of Sinus Node Recovery Time

Many factors in addition to automaticity are involved in the measurement of SNRT, including proximity of the pacing site to the sinus node and conduction time from the pacing site to the sinus node and vice versa, as well as conduction time in and out of the sinus node. Sinus node entrance block during rapid atrial pacing can lead to a shorter SNRT, whereas sinus node exit block after cessation of pacing can result in marked prolongation of the SNRT. Moreover, sometimes SNRT cannot be measured because of atrial ectopic or junctional escape beats that preempt the sinus beat.

Some degree of atrial-nodal block should be suspected when SNRT shortens in response to an increment in the pacing rate or if there is marked variation (more than 250 milliseconds) in the SNRTs when multiple tests are performed at a constant pacing rate.

Despite these limitations, SNRT is probably the best and most widely used test for sinus node automaticity. The durations of the maximum SNRT and corrected SNRT are independent of age. Evaluation of the corrected SNRT following pharmacological denervation (see later) can increase the sensitivity of the test.

Sinus Node Recovery Time in Patients With Sinus Node Dysfunction

The sensitivity of a single SNRT measurement is approximately 35% in patients with SND. This rises to more than 85% when multiple SNRTs at different rates are recorded, along with scatter and total recovery time, with a specificity of more than 90%. A prolonged SNRT or corrected SNRT is found in 35% to 93% of patients suspected of having SND (depending on the population studied). The incidence is lowest in

Fig. 8.8 Sinus Node Recovery Time. Surface electrocardiogram leads and high right atrial (HRA) recordings are shown at the end of a burst of atrial pacing, suppressing sinus node automaticity. The interval at which the first sinus complex returns (SNRT) is abnormally long at 1625 milliseconds. With a baseline sinus cycle length (CL) of 720 milliseconds, the corrected SNRT ($1625 - 720 = 905$ milliseconds) is also prolonged. In addition, there is a secondary pause after the first two sinus complexes.

patients with sinus bradycardia. Marked abnormalities in the corrected SNRT usually occur in symptomatic patients with clinical evidence of sinoatrial block or bradycardia-tachycardia syndrome.³⁷

The PCL at which maximum suppression occurs in patients with SND is unpredictable and, unlike in healthy subjects, tends to be affected by the duration of pacing. However, if sinus entrance block is present, the greatest suppression is likely to occur at relatively long PCLs. If the longest SNRT occurs at PCLs longer than 600 milliseconds, a normal value can reflect the presence of entrance block. In such cases a normal SNRT is an unreliable assessment of sinus node automaticity. The fact that the longest SNRT occurs at PCLs longer than 600 milliseconds is in itself a marker of SND.

Marked secondary pauses are another manifestation of SND and can occasionally occur in the absence of prolongation of SNRT, in which case sinoatrial block is the mechanism. Approximately 69% of patients with secondary pauses have clinical evidence of sinoatrial exit block, and 92% of patients with sinoatrial exit block demonstrate marked secondary pauses.

Sinoatrial Conduction Time

Although the sinus node is the dominant cardiac pacemaker, neither sinus node impulse initiation nor conduction is visible on the surface ECG or on the standard intracardiac recordings because depolarization within the sinus node is of very low amplitude. Therefore sinus node function has usually been assessed indirectly. Normal sinus node function is assumed when the atrial musculature is depolarized at a normal rate and in a normal temporal sequence—so-called *normal sinus rhythm*. In NSR the atrial rate is assumed to correspond to the rate of impulse formation within the sinus node; however, the time of impulse conduction from the sinus node to the atrium cannot be ascertained. Several methods have been developed for the assessment of SACT, either indirectly (the Strauss and Narula methods) or by directly recording the sinus node electrogram. Signal-averaging techniques have also been used to measure SACT noninvasively.³⁷

Direct Recordings

Sinus node depolarization can be recorded directly using high-gain unfiltered electrograms in approximately 50% of patients. A catheter with a 0.5- to 1.5-mm interelectrode distance is used. The catheter is placed directly at the SVC-RA junction, or a loop is formed in the RA and the tip of the catheter is then placed at the SVC-RA junction. Optimizing the filter setting can help to reduce baseline drift (0.1 to 0.6 Hz to 20 to 50 Hz), with signal gain at 50 to 100 mV/cm.

SACT is measured as the interval between the pacemaker prepotential on the local electrogram and the onset of the rapid atrial deflection (Fig. 8.9). When SACT is normal, a smooth upstroke slope merges into the atrial electrogram. When SACT is prolonged, an increasing amount of sinus node potential becomes visible before the rapid atrial deflection. Sinoatrial block is said to occur when the entire sinus node electrogram is seen in the absence of a propagated response to the atrium.

The sinus node electrogram can be validated by the ability to record the electrogram in only a local area, with loss of the upstroke potential during overdrive atrial pacing. In addition, persistence of the sinus node electrogram following carotid sinus massage, following induced pauses, or during pauses following overdrive suppression is an important method for validation.

Strauss Technique

The Strauss technique uses atrial premature stimulation to assess SACT. Baseline sinus beats are designated as A_1 . Progressively premature atrial extrastimuli (A_2) are delivered after every eighth to tenth A_1 , and the timing of the recovery beat (A_3) is measured. The Strauss method

Fig. 8.9 Direct Measurement of Sinoatrial Conduction Time (SACT). A schematic copy of a sinus node electrogram is shown. On the sinus node electrogram, high right atrial depolarization (A), ventricular depolarization (V), T wave (T), and the sinus node potential (SN) are identified. In the second beat, reference lines are drawn through the point at which the SN potential first becomes evident and the point at which atrial activation begins. SACT is the interval between these two reference lines. (From Reiffel JA, Gang E, Gliklich J, et al. The human sinus node electrogram: a transvenous catheter technique and a comparison of directly measured and indirectly estimated sinoatrial conduction time in adults. *Circulation*. 1980; 62:1324–1334.)

is useful as part of an overall EP study when information is also sought on conduction system refractoriness or possible dual AVN physiology or bypass tracts during sinus rhythm. Four zones of response of the sinus node to AES have been identified. SACT can be measured only in the zone of reset (Fig. 8.10).

Zone I: zone of collision. This zone (also referred to as the zone of interference or nonreset zone) is defined by the range of A_1 - A_2 intervals at which the A_2 - A_3 interval is fully compensatory (see Fig. 8.10). Very long A_1 - A_2 intervals (with A_2 falling in the last 20% to 30% of the sinus CL) generally result in collision of the AES (A_2) with the spontaneous sinus impulse (A_1). The sinus pacemaker and the timing of the subsequent sinus beat (A_3) are therefore unaffected by A_2 , and a complete compensatory pause occurs (i.e., A_1 - $A_3 = 2 \times [A_1$ - $A_1]$).

Zone II: zone of reset. The range of A_1 - A_2 intervals at which reset of the sinus pacemaker occurs, resulting in a less than compensatory pause, defines the zone of reset (see Fig. 8.10). Shorter A_1 - A_2 intervals result in penetration of the sinus node with resetting so that the resulting pause is less than compensatory— A_1 - $A_3 < 2 \times (A_1$ - $A_1)$ —but without changing sinus node automaticity. This zone typically occupies a long duration (40% to 50% of the sinus CL). In most patients the A_2 - A_3 interval remains constant throughout zone II, thus producing a plateau in the curve because A_2 penetrates and resets the sinus node, but it does so without changing the sinus pacemaker automaticity. Hence the A_2 - A_3 interval should equal the spontaneous sinus CL (A_1 - A_1) plus the time it takes the AES (A_2) to enter and exit the sinus node. The difference between the A_2 - A_3 and A_1 - A_1 intervals therefore has been taken as an estimate of total SACT (Fig. 8.11).³⁷

Conventionally, it is assumed that conduction times into and out of the sinus node are equal (i.e., $SACT = [A_2$ - $A_3 - A_1$ - $A_1]/2$). However, data suggest that conduction time into the sinus node is shorter than that out of the sinus node (see Fig. 8.11). Thus the Strauss method for assessment of SACT can be affected by the site of stimulation; the farther the site of stimulation is from the sinus node, the greater the overestimation of SACT will be (because conduction through more intervening atrial and perinodal tissue will be incorporated in the measurement). The value of SACT can also be affected by the prematurity of the AES (A_2); the more premature an A_2 is, the more likely it will be to encroach on perinodal or atrial refractoriness and slow conduction

Fig. 8.10 Strauss Sinoatrial Conduction Time Zones. Leads 2 and recording from the high right atrium (HRA) are shown, with a single extrastimulus (S) delivered during sinus rhythm (cycle length, 660 milliseconds) at progressively shorter coupling intervals as indicated relative to the preceding sinus complex. The timing of the subsequent sinus P wave relative to when it would be expected if there were no extrastimulus determines the zone of effect: (A), collision; (B), reset; (C), interpolation; and (D), reentry. See text for details.

Fig. 8.11 Calculation of Sinoatrial Conduction Time (SACT) Using the Strauss Method. The baseline sinus cycle length (A_1-A_2) equals X . The third P wave represents an atrial extrastimulus (A_2) that reaches and discharges the sinoatrial (SA) node, which causes the next sinus cycle to begin at that time. Therefore the A_2-A_3 interval = $X + 2Y$ milliseconds, assuming no depression of sinus node automaticity. Consequently, $SACT = Y = ([A_2-A_3] - [X])/2$. AV, Atrioventricular; ECG, electrocardiogram. (From Olgin JE, Zipes DP: Specific arrhythmias: diagnosis and treatment. In: Libby P, Bonow RO, Mann DL, Zipes DP, eds. *Braunwald's Heart Disease: A Textbook of Cardiovascular Medicine*. 8th ed. Philadelphia, PA: Saunders; 2008:869.)

into the sinus node. In addition, an early AES commonly causes pacemaker shift to a peripheral latent pacemaker, which can exit the atrium earlier because of its proximity to the tissue, thus shortening conduction time out of the sinus node.

Despite those limitations, for practical purposes, the Strauss method is a reasonable estimate of functional SACT, provided that stimulation

is performed as closely as possible to the sinus node and the measurement is taken when a true plateau is present in zone II. SACT appears to be independent of the spontaneous sinus CL. However, marked sinus arrhythmia invalidates the calculation of SACT because it is impossible to know whether the return cycle is a result of spontaneous oscillation or is a result of the AES. To eliminate the effects of sinus arrhythmia, multiple tests need to be performed at each coupling interval. Alternatively, atrial pacing drive at a rate just faster than the sinus rate is used instead of delivery of AES during NSR (Narula method; see later). However, this latter method can result in depression of sinus node automaticity, pacemaker shifts, sinus entrance block, sinus acceleration (if the drive PCL is within 50 milliseconds of sinus CL), and shortening of sinus action potential and can lead to an earlier onset of phase IV; each of these actions can potentially yield misleading results.

In an occasional patient, in response to progressively premature AESs, the A_2-A_3 interval prolongs either continuously or after a brief plateau (in both cases the pause remains less than compensatory). This progressive prolongation of the A_2-A_3 interval during zone II can be caused by suppression of sinus node automaticity, a shift to a slower latent pacemaker, or an increase in conduction time into the sinus node because of encroachment of A_2 on perinodal tissue refractoriness. Thus it is recommended to use the first third of zone II to measure SACT because it is less likely to introduce such errors. Analysis of the A_3-A_4 interval may provide insights into changes in sinus node automaticity or pacemaker shift. If the A_3-A_4 interval is longer than the A_1-A_2 interval, depression of sinus node automaticity is suggested. Therefore the calculated SACT overestimates the true SACT, and correction of SACT is necessary (in which case the A_3-A_4 interval is used as the basic sinus CL with which the A_2-A_3 interval is compared).

Zone III: zone of interpolation. This zone is defined as the range of A_1 - A_2 intervals at which the A_2 - A_3 interval is less than the A_1 - A_1 interval and the A_1 - A_3 interval is less than twice the A_1 - A_1 interval (see Fig. 8.10). The A_1 - A_2 coupling intervals at which incomplete interpolation is first observed define the relative refractory period of the perinodal tissue. Some investigators refer to this as the *sinus node refractory period*. In this case, A_3 represents delay of A_1 exiting the sinus node, which has not been affected. The A_1 - A_2 coupling interval at which complete interpolation is observed probably defines the effective refractory period of the most peripheral of the perinodal tissue because the sinus impulse does not encounter refractory tissue on its exit from the sinus node. In this case, $(A_1-A_2) + (A_2-A_3) = A_1-A_1$, and sinus node entrance block is said to exist.

Zone IV: zone of reentry. This zone is defined as the range of A_1 - A_2 intervals at which the A_2 - A_3 interval is less than the A_1 - A_1 interval and $(A_1-A_2) + (A_2-A_3)$ is less than A_1-A_1 , and the atrial activation sequence and P wave morphology are identical to sinus beats. The incidence of single beats of sinus node reentry is approximately 11% in the normal population.

Narula Method

The Narula method for measuring SACT is simpler than the Strauss technique. Instead of atrial premature stimulation, atrial pacing at a rate slightly faster (10 beats/min or more) than the sinus rate is used as A_2 . It is assumed that such atrial pacing will depolarize the sinus node without significant overdrive suppression. The SACT is then calculated using the same formula as for the Strauss method. The Narula method is the quickest and easiest to perform, but it gives only SACT and does not provide information about the AV conduction system.³⁷

Kirkorian-Touboul Method

In contrast to the Strauss method, which uses progressively premature AESs delivered during NSR to evaluate SACT, the Kirkorian-Touboul method uses progressively premature AESs delivered following an eight-beat pacing train at a fixed rate. This method was designed to determine SACT independently of baseline sinus CL, which can normally be somewhat variable. It can have several advantages, especially for the study of drug effects at identical basic rates, but it is less widely used than the other methods.

Sinoatrial Conduction Time in Patients With Sinus Node Dysfunction

The normal SACT is 45 to 125 milliseconds. There is a good correlation between direct and indirect measurements of SACT in a patient with or without SND. However, SACT is an insensitive indicator of SND, especially in patients with isolated sinus bradycardia. SACT is prolonged in only 40% of patients with SND, and more frequently (78%) in patients with sinoatrial exit block or tachycardia-bradycardia syndrome. In patients with sinus pauses, corrected SNRT is more commonly abnormal than SACT (80% versus 53%). SACT appears to be directly related to the baseline sinus CL, and the sinus node refractory period is directly related to the drive CL.³⁷

Effects of Drugs

Autonomic Blockade (Intrinsic Heart Rate)

Autonomic blockade is the most commonly used pharmacological intervention for evaluation of SND, and it is used to determine the intrinsic heart rate. Autonomic blockade is accomplished by administering atropine, 0.04 mg/kg, and propranolol, 0.2 mg/kg (or atenolol, 0.22 mg/kg). The resulting intrinsic heart rate represents sinus node rate without autonomic influences. The normal intrinsic heart rate is age-dependent and can be calculated using the following equation:

intrinsic heart rate (beats/min) = $118.1 - (0.57 \times \text{age})$. Normal values are $\pm 14\%$ for age younger than 45 years and $\pm 18\%$ for age older than 45 years, and approximately 5 beats/min less for women at all ages. A low intrinsic heart rate is consistent with intrinsic SND. A normal intrinsic heart rate in a patient with known SND suggests extrinsic SND caused by abnormal autonomic regulation. Of note, autonomic blockade with atropine and propranolol also results in shortening of corrected SNRT, as well as sinus CL and SACT.

Atropine

The normal sinus node responses to atropine are an acceleration of heart rate to more than 90 beats/min and an increase over the baseline rate by 20% to 50%. Atropine-induced sinus rate acceleration is usually blunted in patients with intrinsic SND. Failure to increase the sinus rate to more than the predicted intrinsic heart rate following 0.04 mg/kg of atropine is diagnostic of impaired sinus node automaticity. Atropine (1 to 3 mg) markedly shortens SNRT and, in most cases, corrected SNRT. Atropine also abolishes the marked oscillations frequently observed following cessation of rapid pacing. Atropine occasionally results in the appearance of a junctional escape rhythm on cessation of pacing before sinus escape beats in normal subjects (especially in young men with borderline slow sinus rate) and, more commonly, in patients with SND. When this occurs, the junctional escape rhythm is usually transient (lasting only a few beats). Persistence of junctional rhythm and failure of the sinus rate to increase are indicative of SND. Atropine, with or without propranolol, shortens SACT (unrelated to its effects on the sinus rate).

Propranolol

Propranolol (0.1 mg/kg) produces a 12% to 22.5% increase in sinus CL in normal subjects. Patients with SND have a similar chronotropic response to propranolol, a finding suggesting that the sympathetic tone or responsiveness is intact in most patients with SND. Propranolol increases SNRT by 160% in approximately 40% of patients with SND and increases SACT in most patients with SND. The mechanism of these effects is unclear. Effects are minimal in normal subjects.

Isoproterenol/Epinephrine

Isoproterenol (1 to 3 $\mu\text{g}/\text{min}$) or epinephrine (0.05 $\mu\text{g}/\text{kg}$ per min) produces sinus acceleration of at least 25% in normal subjects. An impaired response to isoproterenol correlates well with a blunted chronotropic response to exercise observed in some patients with SND.

Digoxin

Digoxin shortens SNRT or corrected SNRT in some patients with clinical SND, probably because of increased perinodal tissue refractoriness with consequent sinus node entrance block.

Verapamil and Diltiazem

Verapamil and diltiazem have minimal effects on SNRT and SACT in normal persons. Effects in patients with SND have not been studied, but worsening of the SND is expected.

Antiarrhythmic Agents

Procainamide, quinidine, mexiletine, dronedarone, and amiodarone can adversely affect sinus node function in patients with preexisting SND. Severe sinus bradycardia and sinus pauses are the most common problems encountered. Amiodarone is the worst offender and has even caused severe SND in patients without prior evidence of SND. In general, other drugs have minimal effects on sinus node function in normal persons.

PRINCIPLES OF MANAGEMENT

Acute Management

Although pacing is the mainstay of treatment for symptomatic SND, identifying transient or reversible causes for SND is the first step in management. Withdrawal of any offending drugs, correction of any electrolyte abnormalities, and treatment of any extrinsic causes for SND (e.g., obstructive sleep apnea, hypothyroidism, hypoxemia) should be considered prior to permanent pacing therapy. In addition, the specific clinical circumstance in which SND occurred should be analyzed to document potential heightened vagal tone as a cause of sinus bradycardia or pauses. Hypervagotonia as a cause of SND is often suspected by its transient nature and by the symptoms associated with specific clinical circumstances associated with surges in vagal tone, such as vomiting, coughing, gagging, endotracheal intubation, nasogastric tube placement, airway suctioning, and neurocardiogenic syncope. Vagally induced SND may respond to atropine, but it needs to be treated only if the patient is symptomatic.^{33,38} Sinus bradycardia (as low as 30 beats/min) in conditioned athletes is typically benign and does not require further work-up or treatment.³⁴

Pharmacological therapy (atropine, isoproterenol) is effective only as a short-term emergency measure until pacing can be accomplished. Temporary percutaneous or transvenous pacing is necessary in patients with hemodynamically significant bradycardia to provide immediate stabilization prior to permanent pacemaker placement or to provide pacemaker support when the bradycardia is precipitated by what is presumed to be a transient event, such as electrolyte abnormality or drug toxicity.

Chronic Management

After all reversible causes are excluded or treated, correlation of symptoms with ECG evidence of SND is an essential part of the management strategy. Because of the episodic nature of symptomatic arrhythmias, ambulatory monitoring is often required. For the patient with asymptomatic bradycardia or sinus pauses, the long-term prognosis is generally benign, and no treatment is necessary. For symptomatic patients with nonreversible SND, pacing is the mainstay of treatment (Box 8.3). SND is currently the most common reported diagnosis for pacemaker implantation, and it accounts for 40% to 60% of new pacemaker implants.

For symptomatic patients with tachycardia-bradycardia syndrome, pacing may be required to prevent symptomatic bradycardia and allow the use of drug therapy for control of the tachycardia (see Fig. 8.6). These patients are at increased risk for thromboembolism, and the issue of long-term anticoagulation for stroke prevention should be addressed.³⁸ Importantly, in patients with symptomatic paroxysmal AF accompanied by prolonged sinus pauses on AF termination, catheter ablation of AF may be preferred to pacemaker implantation because it can potentially eliminate the arrhythmia as well as the need for permanent pacing.³⁹

No oral drugs with acceptable safety and efficacy profile are currently available for long-term treatment of sinus bradycardia. Chronotropic medications, such as theophylline or aminophylline, have limited efficacy.

Pacemaker Device and Mode Selection

After the decision to pace is made, choosing the optimal pacemaker prescription is essential. Single-chamber atrial or ventricular pacemakers and dual-chamber pacemakers will all prevent bradycardia in the patient with SND; however, each pacemaker type has inherent advantages and disadvantages (Box 8.4).³⁶

In patients with SND but normal AV conduction, physiological pacing can be accomplished with a single-chamber atrial pacemaker (AAI). As compared with dual-chamber pacemakers (DDD), AAI

BOX 8.3 ACCF/AHA/HRS Recommendations for Permanent Pacing in Sinus Node Dysfunction

Class I

- Documented symptomatic bradycardia, including frequent sinus pauses that produce symptoms
- Symptomatic chronotropic incompetence
- Symptomatic sinus bradycardia that results from required drug therapy for medical conditions

Class IIa

- SND with heart rate <40 beats/min when a clear association between significant symptoms consistent with bradycardia and the actual presence of bradycardia has not been documented
- Syncope of unexplained origin when clinically significant abnormalities of SND are discovered or provoked at electrophysiological studies

Class IIb

- Minimally symptomatic patients with chronic heart rate <40 beats/min while awake

Class III

- SND in asymptomatic patients
- SND in patients whose symptoms suggestive of bradycardia have been clearly documented to occur in the absence of bradycardia
- SND with symptomatic bradycardia caused by nonessential drug therapy

ACCF, American College of Cardiology Foundation; AHA, American Heart Association; HRS, Heart Rhythm Society; SND, sinus node dysfunction.

Modified from Epstein AE, DiMarco JP, Ellenbogen KA, et al. 2012 ACCF/AHA/HRS focused update incorporated into the ACCF/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2013;61:e6–75.

pacemakers offer several advantages: simpler implantation, less risk of lead dislodgement, lower initial cost, and avoidance of RV pacing.⁴⁰ However, unlike DDD systems, AAI pacemakers will not prevent ventricular bradycardia if AV block develops. In SND patients the incidence of high-grade AV block requiring ventricular pacing has been estimated at 0.6% to 1.8% per year in patients with apparently normal AV conduction at the time of initial pacemaker placement but significantly higher (7% per year) in those with a complete BBB or bifascicular block at presentation. In a recent report, 9.3% of patients with SND and single-chamber atrial pacemakers required upgrade to a DDD system over a mean follow-up of 5.4 years (1.7% per year), predominantly due to symptomatic AV block or AF with slow ventricular response, despite careful patient selection. Such reoperations were associated with significant complications in up to 16.7% of patients. Advanced age and LA enlargement were predictors for system upgrade.³⁶

Although DDD pacemakers have the capability to maintain AV synchrony and prevent bradycardia from all causes, they are associated with increased incidence of unnecessary RV pacing, which can be hemodynamically detrimental in many patients. Therefore the decision for which system to use is often based on implanting clinician preferences and evidence of baseline AV conduction abnormalities.

Although an AAI pacing system may be considered in the younger patient with SND and no evidence of AV or ventricular conduction abnormalities, in the United States, DDD pacing generally is preferred

BOX 8.4 HRS/ACCF Recommendations for Pacemaker Device and Mode Selection for SND

Class I

- DDD or AAI is recommended over VVI in patients with SND and intact AV conduction.
- Dual-chamber pacing is recommended over single-chamber atrial pacing in patients with SND.

Class IIa

- Rate adaptive pacing can be useful in patients with significant symptomatic chronotropic incompetence, and its need should be reevaluated during follow-up.
- In patients with SND and intact AV conduction, programming dual-chamber pacemakers to minimize ventricular pacing can be useful for prevention of AF.

Class IIb

- AAI pacing may be considered in selected patients with normal AV and ventricular conduction.
- Single-chamber VVI pacing may be considered in instances where frequent pacing is not expected or the patient has significant comorbidities that are likely to influence survival and clinical outcomes.

Class III

- Dual-chamber pacing or single-chamber atrial pacing should not be used in patients in permanent or longstanding persistent AF where efforts to restore or maintain sinus rhythm are not planned.

AAI, single-chamber atrial pacing; ACCF, American College of Cardiology Foundation; AF, atrial fibrillation; AV, atrioventricular; DDD, dual-chamber pacing; HRS, Heart Rhythm Society; SND, sinus node dysfunction; VVI, single-chamber ventricular pacing. Modified from Gillis AM, Russo AM, Ellenbogen KA, et al. HRS/ACCF expert consensus statement on pacemaker device and mode selection. *J Am Coll Cardiol*. 2012;60:682–703.

to single-chamber atrial pacemakers in SND patients due to the concern about progressive AV conduction disease and need for pacemaker upgrade, as well as the lack of evidence that AAI pacing has long-term clinical outcome beneficial effects compared with DDD pacing. In addition, patients who have evidence of abnormal AV conduction prior to pacemaker therapy (up to 20% of SND patients) are not candidates for single-chamber atrial pacing.

On the other hand, single-chamber ventricular pacemakers (VVI) have a limited role in patients with SND because of several disadvantages, including lack of AV synchrony, high burden of RV pacing and ventricular dyssynchrony, as well as increased risk of AF, stroke, and heart failure. Nonetheless, back-up VVI pacing may be considered in sedentary patients, those with significant morbidities and poor clinical prognosis, or when frequent pacing is not expected (e.g., carotid sinus hypersensitivity).³⁶

Pacemaker Syndrome

AV dyssynchrony or suboptimal AV synchrony can cause significant reduction in cardiac output, especially in patients who are particularly sensitive to loss of atrial contribution to ventricular filling, such as those with reduced ventricular compliance and diastolic dysfunction (due to aging or hypertensive, hypertrophic, or restrictive cardiomyopathy) and those with mitral stenosis. Atrial contraction against closed mitral and tricuspid valves (which is further promoted in patients with

intact retrograde ventriculoatrial conduction) can cause uncomfortable pulsation in the neck (cannon a waves) and abdomen, headache, cough, and jaw pain. The resultant increase in LA pressure and left ventricular filling pressure cause increased plasma levels of atrial natriuretic peptide and B-type natriuretic peptide, potent peripheral venous and arterial vasodilators. Furthermore, reduction of cardiac output causes reflex sympathetic activation.³⁶

The combination of detrimental hemodynamic consequences of AV dyssynchrony leads to a constellation of symptoms (including fatigue, weakness, effort intolerance, chest discomfort, dyspnea, confusion, dizziness, presyncope, or syncope) known as “pacemaker syndrome.” Although pacemaker syndrome can occur with any pacing mode, it occurs most commonly with VVI pacing in patients who are in sinus rhythm (reported in up to 83%). Severe symptoms warranting reprogramming from VVI to DDD pacing has been needed in 25% to 30% of these patients.⁴⁰

Minimizing Right Ventricular Pacing

A high percentage of RV pacing (>40%) can cause cardiomyopathy and heart failure secondary to ventricular dyssynchrony due to an abnormal activation sequence. In addition, frequent ventricular pacing, even in an AV synchronous pacing mode, increases the risk and burden of AF, likely secondary to ventricular dyssynchrony and systolic dysfunction. As compared with ventricular pacing, atrial or dual-chamber pacing significantly reduces AF, with relative risk reductions of 18% to 46%, as well as a significant reduction in the risk of stroke.^{36,41}

Therefore minimizing unnecessary RV pacing should be a goal in SND patients treated with pacemaker therapy. This can be achieved by programming longer AV delays or turning off rate response (in patients with single-chamber ventricular devices or in those with dual-chamber pacemakers in whom faster atrial pacing causes unacceptably long paced PR interval or AVB). In addition, contemporary pacemakers offer a variety of algorithms designed to give preference to intrinsic ventricular activation, thereby minimizing the adverse effects of unnecessary RV pacing, including AV search hysteresis (AVSH) and managed ventricular pacing (MVP).⁴²

AVSH, the most widely used algorithm, searches for intrinsic AV conduction by periodically and incrementally extending the AV interval to a prespecified maximum (which allows the avoidance of nonphysiologic AV delays). If intrinsic conduction is detected, the AV delay remains extended to give priority to intrinsic AV conduction; otherwise, the device returns to the baseline programmed AV delay.

The MVP algorithm provides functional AAIR pacing with ventricular monitoring and an automatic switch from AAIR to DDDR during episodes of AV block. However, in some patients the benefit of these algorithms in minimizing RV pacing can be counteracted by the deleterious effects of excessively long native or paced PR intervals or bradycardia. Severe first-degree AV conduction delay can potentially cause worsening of heart failure symptoms. Even in apparently healthy adults, prolongation of the PR interval was found to be associated with higher risk of AF and heart failure.⁴³ In addition, the timing cycles in the MVP algorithm can predispose to short-long-short ventricular sequences, which can be proarrhythmic in vulnerable patients. Therefore the use of these algorithms must be individualized.

Recently, a pacing mode that combines atrial preventive pacing and atrial antitachycardia pacing (DDDRP) plus MVP algorithms was found to effectively promote intrinsic ventricular activation, thereby minimizing the adverse effects of unnecessary RV pacing. This combination was associated with 61% reduction of the risk of progression to permanent AF on 2-year follow-up in patients with bradycardia and paroxysmal or persistent atrial tachyarrhythmias when compared with standard DDDR pacing mode.⁴⁴

These algorithms often produce unanticipated findings on ECG monitoring (i.e., varying AV intervals, occasional P waves that are neither conducted nor tracked with paced complexes). It is important for those reviewing monitor strips to know whether these algorithms are operative and interpret them correctly and thereby avoid unnecessary intervention (pacemaker revision) on a system that is functioning normally.

Rate Adaptive Programming

All contemporary pacemakers have rate-adaptive algorithms to mimic the physiological chronotropic response for patients with SND. Several parameters have been investigated to estimate metabolic need and heart rate requirements for rate-adaptive algorithms, including: (1) accelerometer; (2) minute ventilation; and (3) closed-loop stimulation, and they vary according to pacemaker manufacturer and model.

The most widely used rate-adaptive algorithms use an accelerometer coupled with piezoelectric sensors that increase pacing rate according to the amount and vigorousness of anterior to posterior thoracic motion. Certain pacemakers have the capacity to estimate minute ventilation (which correlates with oxygen consumption and cardiac output) by measuring transthoracic impedance from a rapid, low-amplitude current impulse applied between the lead tip and pulse generator. Measured changes in minute ventilation trigger changes in pacing rates. Pacemakers with closed-loop stimulation algorithms estimate cardiac sympathetic activation by measuring changes in the unipolar RV impedance, which correlates to changes of the RV contractility and reflects the level of cardiac sympathetic activity. An increase in intracardiac impedance (and cardiac contractility) is used to indicate a need for increased heart rate. Importantly, each algorithm is associated with inherent advantages and disadvantages, and none is able to accurately predict the physiological chronotropic response in all different physiological scenarios or to completely eliminate the risk of unnecessary pacing.³⁶

Although some studies found rate-responsive algorithms superior to fixed-rate pacing in improving exercise capacity in patients with chronotropic incompetence, other studies raised the concern of increased risk of heart failure and AF associated with a higher percentage of atrial pacing. In addition, in some patients, atrial pacing can cause excessive prolongation of PR intervals or second-degree AVB and as a result a high percentage of RV pacing. Furthermore, faster pacing rates, even at levels that are appropriate to the physiological need in normal subjects, can have detrimental effects in patients with ischemic heart disease or heart failure.⁴⁵ Hence rate-adaptive programming is recommended only for patients with chronotropic incompetence who experience symptomatic benefit in response to rate adaptive pacing. The need for rate-adaptive programming should be evaluated periodically to help minimize unnecessary pacing.

Mode Switch Algorithms

Automatic mode switching (AMS) algorithms reprogram the pacemaker from an atrial tracking (DDD or DDDR) to a nontracking mode (VVI, VVIR, DDI, or DDIR) on sensing an atrial tachyarrhythmia and back again to DDD or DDDR mode when a normal atrial rate is sensed. This helps to avoid rapid ventricular pacing in response to atrial tachyarrhythmias or other rapidly occurring signals sensed by the atrial channel.

The accurate detection of atrial tachyarrhythmias depends on the rate of the detected atrial arrhythmia compared with the programmed AMS rate, the length of the atrial blanking and refractory periods, and the programmed atrial sensitivity. Reduced sensitivity can occur due to AF with small electrogram amplitudes, slower atrial tachycardias, or blanked atrial waves during AFL. On the other hand, false-positive mode switching can result from oversensing of ventricular far-field signals or, rarely, myopotentials. Hence optimal pacemaker programming requires a thorough knowledge of the patient's arrhythmia history,

atrial electrogram amplitude (in sinus rhythm and atrial tachyarrhythmia), atrial rates during the arrhythmia, and the characteristics of the AMS algorithm used in the specific pacemaker make and model.³⁶

Overall, the performance of AMS algorithms has been quite satisfactory, and the data provided by these programs on the time of onset and duration of AMS episodes can generally be used as a reliable surrogate marker for the occurrence and burden of atrial tachyarrhythmias and help to guide clinical decisions regarding the need and efficacy of antiarrhythmic interventions or the risk of thromboembolic events. If clinical decisions are being contemplated based on these findings, interrogation and analysis of stored electrograms during available AMS episodes should be considered to verify the reliability of these algorithms.³⁶

ANATOMY AND PHYSIOLOGY OF THE ATRIOVENTRICULAR JUNCTION

Internodal and Interatrial Conduction

Evidence suggests the presence of preferential impulse propagation from the sinus node to the atrioventricular node (AVN) (i.e., higher conduction velocity between the nodes in some parts of the atrium than in other parts). However, whether preferential internodal conduction is caused by fiber orientation, size, or geometry or by the presence of specialized preferentially conducting pathways located between the nodes has been controversial. It is believed by many that there are three preferential anatomic conduction pathways from the sinus node to the AVN: anterior, posterior, and middle. However, ultrastructural evidence for discrete bands of rapidly conducting myocytes is sparse, and it is more likely that preferential conduction occurs over muscle bundles and not discrete internodal tracts. These groups of internodal tissue are best referred to as *internodal atrial myocardium*, not tracts, because they do not appear to be histologically recognizable specialized tracts, only plain atrial myocardium. In addition, detailed electroanatomic activation maps do not reveal more rapidly conducting tracts.¹

The anterior “internodal atrial myocardium” begins at the anterior margin of the sinus node, curves anteriorly around the superior vena cava (SVC) to the interatrial septum, and then splits into two bundles: one passes to the left atrium (LA) (Bachmann bundle), while the second bundle descends along the interatrial septum and connects to the superior margin of the AVN. The Bachmann bundle is a large, flat muscle bundle that appears to conduct the cardiac impulse preferentially from the right atrium (RA) to the LA. It connects the anterosuperior RA and

LA behind the ascending aorta, just beneath the epicardium, and is recognized as the preferential path of LA activation during sinus rhythm. Histologically, the Bachmann bundle has characteristics of atrial myocardium and is considered the main, but not the exclusive, route of interatrial conduction.² Three other interatrial conduction pathways have been described: muscular bundles on the inferior atrial surface near the coronary sinus (CS), transseptal fibers in the fossa ovalis, and posteriorly in the vicinity of the right pulmonic valves (PVs).^{3,4}

The middle “internodal atrial myocardium” begins at the superior and posterior margins of the sinus node, travels posteriorly behind the SVC to the crest of the interatrial septum, and descends within the interatrial septum to the superior margin of the AVN. The posterior “internodal atrial myocardium” starts at the inferoposterior margin of the sinus node, travels inferiorly through the crista terminalis to the eustachian ridge, and then into the interatrial septum above the CS os, where it joins the posterior portion of the AVN. Some fibers from all three pathways bypass the crest of the AVN and enter its more distal segment.

Central Fibrous Body

The cardiac skeleton consists of four rings of dense connective tissue that surround the AV canals (mitral and tricuspid) and extends to the origins of the aorta and the pulmonary trunk. The aortic valve occupies the central position with the other valve rings attached to it. The triangular formation between the aortic valve and the medial parts of the tricuspid and mitral valves is the right fibrous trigone, which represents the largest thickening and strongest portion of the cardiac skeleton (Fig. 9.1). The right fibrous trigone, together with the membranous

Atrioventricular Node

The AVN is an interatrial structure, measuring approximately 5 mm long, 5 mm wide, and 0.8 mm thick in adults. The AVN is located beneath the RA endocardium at the apex of the triangle of Koch, anterior to the CS os and directly above the insertion of the septal leaflet of the tricuspid valve, where the tendon of Todaro merges with the central fibrous body. Slightly more anteriorly and superiorly is where the His bundle (HB) penetrates the AV junction through the central fibrous body and the posterior aspect of the membranous AV septum. The compact node is adjacent to the central fibrous body on one side but is uninsulated by fibrous tissue on its other sides, thus allowing contiguity with the atrial myocardium. When traced inferiorly, toward the base of the triangle of Koch, the compact AVN area separates into two (rightward and leftward) posterior extensions, usually with the artery supplying the AVN running between them. These prongs bifurcate toward the tricuspid and mitral annuli, respectively. The rightward posterior extension has been implicated in the so-called slow pathway in the typical atrioventricular nodal reentry tachycardia (AVNRT) circuit.^{2,6,7}

The normal AV junctional area can be divided into distinct regions: the transitional cell zone (which represents the approaches from the working atrial myocardium to the AVN), the compact AVN, and the penetrating part of the HB. The AVN and perinodal area are composed of at least three electrophysiologically distinct cells: the atrionodal (AN), nodal (N), and nodal-His (NH) cells. The AN region corresponds to the cells in the transitional region that are activated shortly after the atrial cells.^{6,7} The N region corresponds to the region where the transitional cells merge with midnodal cells. The N cells represent the most typical of the N cells, which are smaller than atrial myocytes, are closely grouped, and frequently are arranged in an interweaving fashion. Sodium (Na^+) channel density is lower in the midnodal zone of the AVN than in the AN and NH cell zones, and the inward L-type calcium (Ca^{2+}) current is the basis of the upstroke of the N cell action potential. Therefore conduction is slower through the N region in the compact AVN than in the AN and NH cell zones. In addition, the N cells exhibit diastolic depolarization and are capable of automatic impulse formation.¹ The N cells in the compact AVN appear to be responsible for the major part of AV conduction delay and exhibit decremental properties in response to premature stimulation because of their slow rising and longer action potentials. They are likely the site of Wenckebach block and the site at which calcium channel blockers delay AV conduction. Fast pathway conduction through the AVN apparently bypasses many of the N cells by transitional cells, whereas slow pathway conduction traverses the entire compact AVN. Importantly, the recovery of excitability after conduction of an impulse is faster for the slow pathway than for the fast pathway, for reasons that are unclear.¹ The NH region corresponds to the lower N cells, typically distal to the site of Wenckebach block, connecting to the insulated penetrating portion of the HB. The action potentials of the NH cells are closer in appearance to the fast-rising and long action potentials of the HB.²

The AVN is the only normal electrical connection between the atria and the ventricles; the fibrous skeleton acts as an insulator to prevent electrical impulses from entering the ventricles by any other route. The main function of the AVN is modulation of atrial impulse transmission to the ventricles; it introduces a delay between atrial and ventricular systole, thereby allowing atrial systole and ventricular filling to complete prior to initiation of ventricular systole.¹ Another primary function of the AVN is to limit the number of impulses conducted from the atria to the ventricles. This function is particularly important during fast atrial rates (e.g., during AF or atrial flutter [AFL]), in which only a portion of impulses are conducted to the ventricles and the remaining

impulses are blocked in the AVN. In addition, fibers in the lower part of the AVN can exhibit automatic impulse formation, serving as a subsidiary pacemaker.^{6,7}

The AVN region is innervated by a rich supply of cholinergic and adrenergic fibers. Sympathetic stimulation shortens AVN conduction time and refractoriness, whereas vagal stimulation prolongs AVN conduction time and refractoriness. The negative dromotropic response of the AVN to vagal stimulation is mediated by activation of the inwardly rectifying potassium (K^+) current (IK_{ACh}), which results in hyperpolarization and action potential shortening of AVN cells, increased threshold of excitation, depression of action potential amplitude, and prolonged conduction time. The positive dromotropic effect of sympathetic stimulation arises as a consequence of activation of the L-type Ca^{2+} current.

The blood supply to the AVN predominantly comes via the AV nodal artery, a branch of the right coronary artery in approximately 90% of hearts and from the circumflex artery in 10%.

His Bundle

The HB connects with the distal part of the compact AVN and penetrates the central fibrous body (where it is called the “nonbranching” or “penetrating” bundle) in a leftward direction (away from the RA endocardium and toward the crest of the muscular interventricular septum). The HB then emerges on the crest of the ventricular septum and continues sandwiched between the muscular and the membranous components of the septum for 1 to 2 cm before dividing into the right and left bundle branches. Viewed from the aorta, the HB passes beneath the part of the membranous septum that adjoins the interleaflet fibrous triangle between the right and non-CSs. The HB is insulated from the atrial myocardium by the membranous septum and from the ventricular myocardium by connective tissue of the central fibrous body, thus preventing atrial impulses from bypassing the AVN. Proximal cells of the penetrating portion of the HB are heterogeneous and resemble those of the compact AVN; distal cells are larger, similar to cells in the proximal bundle branches and ventricular myocytes.^{1,8,9}

The HB is supplied by the AV nodal artery and the first septal branch of the left anterior descending artery. The dual blood supply makes the conduction system at this site less vulnerable to ischemic damage unless the ischemia is extensive.

The AVN and the HB region are innervated by a rich supply of cholinergic and adrenergic fibers, with a density exceeding that found in the ventricular myocardium. Although neither sympathetic stimulation nor vagal stimulation affects normal conduction in the HB, either can affect abnormal AV conduction.

PATHOPHYSIOLOGY OF ATRIOVENTRICULAR BLOCK

Block or delay of a cardiac impulse can take place anywhere in the heart or even within a single cell. AV block can be defined as a delay or interruption in the transmission of an impulse from the atria to the ventricles caused by an anatomical or functional impairment in the conduction system. The conduction disturbance can be transient or permanent.

Congenital and Inherited Atrioventricular Block

Congenital Atrioventricular Block

Congenital complete AV block is thought to result from embryonic maldevelopment of the AVN (and, much less frequently, the His-Purkinje system [HPS]), resulting in a lack of connection between the atria and the peripheral conduction system, with fatty replacement of the AVN and nodal approaches. The incidence of congenital complete AV block

varies from 1 in 15,000 to 1 in 22,000 live births. The defect usually occurs proximal to the HB and is associated with a stable escape rhythm (greater than 60 beats/min) with a narrow QRS complex.^{10,11}

In 60% to 90% of cases, congenital AV block is associated with neonatal lupus caused by passively acquired autoimmune disease in which maternal autoantibodies to the intracellular ribonucleoproteins Ro (SS-A) and La (SS-B) cross the placenta and injure the previously normal fetal heart. These antibodies can be seen with subclinical or clinical maternal lupus erythematosus, maternal Sjögren syndrome, and other maternal autoimmune diseases. The exact mechanism by which these autoantibodies can cause AV block or other cardiac abnormalities is uncertain. Involvement of the AV conduction system produces different degrees of AV block. Although first-degree AV delay can be transient, complete AV block is irreversible. The risk of the fetus developing congenital atrioventricular block (AVB) in a single anti-Ro- or anti-La-positive pregnancy is relatively low (1% to 2%), but the risk in the same mother increases significantly (12% to 20%) in subsequent pregnancies. Although the severity of AV block can vary, most cases diagnosed in utero present with second- or third-degree block.^{12,13}

Approximately one-third of patients with congenital AV block have concurrent congenital heart disease (e.g., congenitally corrected transposition of the great vessels, AV discordance, ventricular septal defects, AV canal defects, tricuspid atresia, anomalous left coronary artery arising from the pulmonary artery, or Ebstein anomaly of the tricuspid valve). The AV conduction system can be displaced if atrial and ventricular septa are malaligned, AV arrangements are discordant, or the heart is univentricular. In general, if the AV conduction system is displaced, it will also tend to be more fragile and susceptible to degeneration, thus placing patients at greater risk for AV block.¹⁴

Hereditary Cardiac Conduction Disease

Progressive cardiac conduction disorder is an inherited cardiac disease that can present as a primary electrical disease or be associated with structural heart disease. Mutations in genes encoding cardiac ion channels, ion channel-interacting proteins, cardiac transcription factors, and cytoskeletal elements have been described as a rare cause of familial forms of AV block (see Chapter 2). Disease can occur at any level of the cardiac conduction system and can manifest as sinoatrial exit block, AV block, or bundle branch block (BBB).^{15,16,17}

Loss-of-function mutations in the *SCN5A* gene (encoding the alpha subunit of the cardiac Na⁺ channel) cause the majority of familial forms of progressive cardiac conduction disease (referred to as hereditary Lenègre disease, primary cardiac conduction system disease, and familial AV block). This disease is characterized by slowing of electrical conduction through the atria, AVN, HB, Purkinje fibers, and ventricles, accompanied by an age-related degenerative process and fibrosis of the cardiac conduction system, in the absence of structural or systemic disease. It is often reflected by varying degrees of AV block and BBB. A single loss-of-function *SCN5A* mutation can cause isolated progressive cardiac conduction disease or can be combined with the Brugada syndrome (overlap syndrome). Furthermore, loss-of-function mutations in the *SCN1B* gene (encoding the beta₁ and beta_{1b} subunits of the Na⁺ channel) have been identified in patients with progressive cardiac conduction disease who carried no mutation in *SCN5A*.^{13,18}

Mutations in the gene *TRPM4* gene (encoding the calcium-activated nonselective cation channel of the transient receptor potential melastatin, which is highly expressed in cardiac Purkinje fibers) have been associated with isolated progressive cardiac conduction block.

Another channelopathy that has been associated with conduction system disorders is the LQT7, or Andersen-Tawil syndrome, caused by mutations in the *KCNJ2* gene (encoding the inward rectifier *Kr*2.1, a critical component of the cardiac inward K⁺ rectifier current, *I_{K1}*).

In addition, mutations in the *PRKAG2* gene (encoding the gamma₂ regulatory subunit of adenosine monophosphate-activated protein kinase) have been described in patients with Wolff-Parkinson-White syndrome and AV conduction block.¹⁸ Recently, mutations in *GJA5* gene (encoding for connexin 40 protein) were linked to progressive familial heart block and malignant ventricular arrhythmias.¹⁵

Neuromyopathies

Neuromuscular disorders represent a diverse collection of inherited diseases affecting skeletal muscle, frequently caused by mutations in genes encoding cytoskeletal, nuclear envelope (e.g., lamin A/C and emerin), or mitochondrial proteins. Cardiac involvement is common and usually manifests as dilated or hypertrophic cardiomyopathy (HCM), AV conduction abnormalities, and atrial and ventricular dysrhythmias. AV conduction disturbances are usually the major cardiac manifestation of Becker muscular dystrophy, peroneal muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy, and myotonic muscular dystrophy. Progression of AV block is unpredictable and can be an important cause of mortality in such cases.¹⁸

Long-QT Syndrome

In long-QT syndrome (LQTS) with a very long QT interval (e.g., in LQT2, LQT3, LQT8, and LQT9), functional block between the HB and ventricular muscle caused by prolonged ventricular refractoriness can lead to 2:1 AV block and severe bradycardia. In addition, conduction abnormalities of the HPS, including PQ prolongation and right bundle branch block (RBBB) or left bundle branch block (LBBB), can occur in some patients with LQTS.

Acquired Atrioventricular Block

Drugs

Various drugs can impair conduction and cause AV block. Digoxin and beta blockers act primarily indirectly on the AVN through their effects on the autonomic nervous system. Calcium channel blockers and other antiarrhythmic drugs, such as amiodarone and dronedarone, act directly to slow conduction in the AVN. Class I and III antiarrhythmic drugs can also affect conduction in the HPS and cause infranodal block. However, these effects typically occur in patients with preexisting conduction abnormalities. Patients with a normal conduction system function rarely develop complete heart block as a result of using antiarrhythmic agents. Other agents that can produce AV conduction disturbances include clonidine, lithium (in toxic concentrations), and fingolimod (usually transient).

Ischemic Heart Disease

AV block occurs in 12% to 25% of all patients with acute ST-elevation myocardial infarction (MI); first-degree AV delay occurs in 2% to 12%, second-degree AV block occurs in 3% to 10%, and third-degree AV block occurs in 3% to 7%.

First-degree AV delay and type 1 second-degree (Wenckebach) AV block occur more commonly in inferior MI, usually caused by increased vagal tone (Bezold-Jarisch reflex), rather than direct nodal ischemia, and generally associated with other signs of vagotonia, such as sinus bradycardia and responsiveness to atropine and catecholamine stimulation. Wenckebach AV block in the setting of acute inferior MI is usually transient (resolving within 48 to 72 hours of onset) and asymptomatic and rarely progresses to more advanced degrees of AV block. Wenckebach AV block occurring later in the course of acute inferior MI is less responsive to atropine and probably is associated with ischemia of the AVN.

Type 2 second-degree (Mobitz type II) AV block occurs in only 1% of patients with acute MI (more commonly in anterior than inferior

MI) and has a worse prognosis than type 1 second-degree block. Type 2 second-degree AV block occurring during acute anterior MI is typically associated with HB or bundle branch ischemia or infarction and frequently progresses to complete heart block.

The incidence of new-onset, high-grade AV block in patients complicating ST elevation MI has decreased in the reperfusion era from 5% to 7% with thrombolytic therapy to 2.2% with primary percutaneous coronary intervention. The risk is even less in non-ST elevation MI. Predictors of AV block in acute MI patients include older age, female gender, inferior acute MI, prior MI, smoking, hypertension, and diabetes. Furthermore, the risk is 2 to 4 times higher in acute inferior MI as compared with anterior MI (9.4% vs. 2.5% in the thrombolytic era). In patients undergoing primary percutaneous coronary intervention, the incidence of high-grade AV block is approximately 7% when the culprit lesion is in the right coronary artery, compared with 1% when the culprit lesion is in the left anterior descending artery.^{19,20,21}

High-degree AV block complicating acute MI is an ominous prognostic marker and is independently associated with 3 times higher in-hospital and 30-day mortality as compared with those with preserved AV conduction, irrespective of the site of the infarction or LV function. This markedly adverse prognostic impact of high-grade AV block has not been reduced by primary percutaneous coronary intervention as compared with thrombolytic therapy or even to prethrombolytic era.²² The negative prognostic impact of complete AV block is greater in patients with anterior than those patients with inferior ST elevation MI.²¹ The risk of death is higher in patients with occlusion of the left anterior descending artery as compared with those with right coronary artery occlusion (55% vs. 36%). Importantly, AV block itself is not responsible for the increased mortality but rather is a marker for a more extensive infarct size. Similar to observations from the prethrombolytic era, the occurrence of high-degree AV block during acute MI has no impact on 1-year mortality among 30-day survivors.^{19,20} Of note, new-onset intraventricular conduction disturbances complicate 10% to 20% of anterior MI (with or without AV block) and are usually associated with high mortality due to the extensive myocardial necrosis (rather than the conduction disturbance).

High-grade AV block develops upon hospital admission in more than half of patients with this complication and within 48 hours after admission in the majority patients. The block is typically transient, most often resolves spontaneously within a few days or weeks, with only 9% of these patients requiring pacemaker implantation prior to hospital discharge.^{19,20}

Of note, in the thrombolytic era, thrombolytic therapy frequently precipitated transient AV block, likely due to enhanced vagal tone secondary to reperfusion. Whether this effect is different when reperfusion is achieved by intracoronary stenting is unknown.

Acute Inferior Myocardial Infarction

In the setting of acute right coronary artery occlusion, AV block is almost always (90% of the patients) located above the HB. The block often progresses gradually (from first-degree, to type 1 second-degree, to complete AVB) and is associated with a junctional escape rhythm with a narrow QRS complex (in 70% of cases) and a rate of 40 to 60 beats/min. Complete AVB occurring in the early phase of acute inferior MI (within 6 hours of onset of symptoms) is more likely related to enhanced vagal tone, tends to be reversed by vagolytic drugs or catecholamines, and usually resolves within several days. In contrast, AV block developing later in the course of acute inferior MI tends to be more persistent and is more likely related to ischemia of the AVN (hypoperfusion of the AVN artery). Small areas of focal necrosis can occur; however, complete infarction and necrosis of the AVN or occlusion of the AVN artery are rare.^{23,20}

Acute Anterior Myocardial Infarction

Development of complete AV block in the setting of acute anterior MI is usually a marker of a large infarct area and hence is commonly associated with a higher risk of VT and VF, hypotension, pulmonary edema, and in-hospital mortality. Frequently, these patients have extensive infarction of the septum and anterior wall in the presence of severe multivessel disease involving both the left anterior descending artery and the right or a dominant left circumflex coronary artery.

In the setting of anterior MI, AV block is most often located below the AVN and is usually associated with ischemia or infarction of the HB or bundle branches (related to interruption of septal perfusion) and is less likely to be reversible. Complete AV block during acute anterior MI generally occurs abruptly during the first 24 hours after MI and often is preceded by the development of a new RBBB, fascicular block, or type 2 second-degree AV block. The escape rhythm usually originates from the bundle branch and Purkinje system, with a rate less than 40 beats/min and a wide QRS complex, with higher risk of ventricular asystole.^{23,20}

Chronic Ischemic Heart Disease

Chronic ischemic heart disease, with or without infarction, can result in persistent AV block secondary to fibrotic changes in the bifurcating HB and bundle branches. Transient AV block can occasionally occur during angina pectoris whether due to atherosclerosis or spasm in relatively normal caliber vessels (Prinzmetal angina).

Degenerative Diseases

Fibrosis and sclerosis of the conduction system are the most common causes of acquired conduction system disease. These disorders account for approximately half the cases of AV block in adults and can be induced by several different conditions, which often cannot be distinguished clinically.

Progressive cardiac conduction disease (including Lev disease or Lenègre disease) manifests as progressive slowing of electrical conduction through the atria, AVN, HB, Purkinje fibers, and ventricles, accompanied by an age-related degenerative process, in which fibrosis affects only the cardiac conduction system. Complete AV block can develop and cause syncope or sudden death. Lev disease is a result of proximal bundle branch calcification or fibrosis and is often described as senile degeneration of the conduction system. Its postulated cause is a hastening of the aging process by hypertension and arteriosclerosis of the blood vessels supplying the conduction system. Lenègre disease is a sclerodegenerative process that occurs in a younger population and involves the more distal portions of the bundle branches. As noted, an inherited form of progressive cardiac conduction disease has been identified, whereby conduction slowing may be attributed to loss-of-function mutations in the *SCN5A* gene. Whether the age-dependent fibrosis of the conduction system is a primary degenerative process in progressive cardiac conduction disease or a physiological process that is accelerated by I_{Na} reduction remains to be investigated.¹⁸

Calcification of the aortic or (less commonly) mitral valve annulus can extend to the nearby conduction system and produce AV block. As noted, the HB penetrates the central fibrous body adjacent to the fibrous continuity between the aortic and mitral valves that is the usual site of dystrophic calcification, and extension of calcification can directly involve the HB and the origin of the left bundle branch.

Rheumatic Diseases

AV block can occur in association with collagen vascular diseases such as scleroderma, rheumatoid arthritis, Reiter syndrome, systemic lupus erythematosus, ankylosing spondylitis, and polymyositis. Polyarteritis nodosa and Wegener granulomatosis also can cause AV block.

Infectious Diseases

Infective endocarditis (especially of the aortic valve) and myocarditis of various viral, bacterial, and parasitic causes (including Lyme disease, Chagas disease, rheumatic fever, tuberculosis, measles, and mumps) can cause varying degrees of AV block.

In the setting of infective endocarditis, AV block and BBB can develop due to perivalvular extension complicating aortic valve involvement and typically predict poor prognosis. Lyme disease involves the heart in 1% to 2% of cases. AV block (ranging from asymptomatic first-degree AV delay to complete AV block, typically intranodal) is the most common manifestation of Lyme carditis. The degree of AV block can fluctuate rapidly over minutes to hours and days. In the majority of patients, AV block is a transient phenomenon and typically resolves completely within 1 to 6 weeks. Resolution of AV block is usually gradual, from complete heart block, to Wenckebach AV block, to first-degree AV delay.²⁴ Although temporary pacing can be required in some patients, implantation of a permanent pacemaker is not recommended.²⁵ Hence Lyme disease should be excluded prior to considering permanent pacemaker implantation in young patients in endemic areas who present with complete AV block. In Chagas disease, conduction system abnormalities, most frequently RBBB or left anterior fascicular (LAF) block, and various degrees of AV block are observed in approximately 36% of patients. Complete AV block can develop in more than 8% and is correlated with increased mortality.²⁶

Infiltrative Processes

Infiltrative cardiomyopathies such as amyloidosis, sarcoidosis, hemochromatosis, and tumors can be associated with AV block. Cardiac involvement occurs in more than 25% of the patients with pulmonary/systemic sarcoidosis but frequently remains asymptomatic. Symptomatic cardiac involvement occurs in approximately 5% of sarcoidosis patients. Various conduction abnormalities can develop as a result of granulomatous infiltration (with inflammation and subsequent scarring) of the basal interventricular septum and conduction system or involvement of the nodal artery causing ischemia in the conduction system.²⁷ BBB (more commonly RBBB) has been observed 12% to 32% of cases of cardiac sarcoidosis and complete AV block in 23% to 30%.²⁸ AV block can manifest early or late in the course of the disease and occasionally can be the first clinical manifestation of sarcoidosis involving any organ. In early stages, before scar formation, AV block can be reversible with immunosuppression therapy. However, permanent pacing is frequently required. In these patients, because AV block likely signifies extensive cardiac disease and portends a higher risk of future ventricular arrhythmias, implantation of an implantable cardioverter-defibrillator (for the primary prevention of sudden cardiac death) instead of a pacemaker needs to be considered, regardless of left ventricular ejection fraction (LVEF) or prior occurrence of ventricular arrhythmias.²⁸ Cardiac sarcoidosis should be suspected in young patients (especially black patients) who present with complete AV block, even in those who do not carry a previous diagnosis of extracardiac sarcoidosis.

Atrioventricular Block in Athletes

AV block occurs in highly conditioned athletes, probably an expression of hypervagotonia related to physical training, and is usually correlated to type and intensity of training. First-degree AV delay has been observed in up to 40% of athletes and type 1 second-degree block in up to 22%. Other signs of hypervagotonia (e.g., sinus bradycardia, respiratory sinus arrhythmia, wandering pacemaker, and junctional bradycardia) are also more common in this population, but AV block can develop without significant sinus bradycardia because the relative effects of sympathetic and parasympathetic systems on the AVN and sinus node can differ. First-degree and Wenckebach AV block in athletes is usually benign,

asymptomatic, resolves with aerobic exercise (as vagal tone is withdrawn), and frequently disappears or decreases after deconditioning.²⁹ Therefore further diagnostic evaluation is not required. In contrast, AV block that does not respond to exercise or atropine, and type II second-degree and complete AV block are rare in athletes, and their presence should prompt careful evaluation and management.

Iatrogenic Atrioventricular Block

Intracardiac catheter manipulation can inadvertently produce varying degrees of heart block, which is usually temporary. Complete heart block can occur during right-sided heart catheterization in a patient with preexisting LBBB or during LV catheterization (LV angiography or ablation procedures) in a patient with preexisting RBBB. Catheter trauma has been reported to cause AV nodal block, as well as block in each of the fascicles of the conduction system; although most blocks are transient, catheter-induced LBBB may persist. AV block can also be a complication of catheter ablation of AVNRT, BTs, and ATs in the AVN vicinity, as well as VTs originating in the interventricular septum adjacent to the HB. Rarely, ablation on the left side of the interatrial septum can damage AVN conduction.

Cardiac surgery can be complicated by varying degrees of AV block caused by trauma and ischemic damage to the conduction system. Mechanical trauma to the conduction system is more common in valvular surgeries, septal myectomy for HCM, or repair of basal ventricular septal defect. Ischemic injury can occur as a result of inadequate myocardial protection during surgery. Not infrequently, the block is temporary and is thought to be secondary to postoperative local inflammation. However, AV block can appear years later, usually in patients who had transient block just after the operation.

AV block occurs with an overall incidence of 1% to 3% after surgical procedures for congenital heart disease and 0.8% to 2.1% after non-congenital cardiac surgeries. Significant risk factors for high-degree AVB include older age, preoperative AV and intraventricular conduction abnormalities, AF, valvular surgery (except pulmonic), and cardiopulmonary bypass time.^{14,30}

Congenital heart disease substrates associated with a relatively high prevalence of postoperative AV block include displaced AV conduction systems (congenitally corrected transposition of the great arteries, AV septal defects), ventricular septal defect, and subaortic stenosis. AV block resolves within 7 to 10 days in 50% of patients.^{14,31}

Complete or high-degree AVB requiring permanent pacing complicates approximately 0.6% of coronary bypass surgeries, 4.5% of cardiac transplant surgeries, and 1.5% after mitral valve repair or replacement surgeries. The incidence is higher (7.7%) after redo valve surgeries. In patients with HCM, persistent AV block complicates 14% to 22% septal alcohol ablation procedures and 2% of surgical myectomy.³²

The close anatomical proximity of the aortic valve annulus, AVN, and HB makes the AV conduction system especially vulnerable to injury during prosthetic aortic valve procedures. The incidence of AV block postsurgical aortic valve replacement is approximately 6%.³³ Predictors indicating the need for a permanent pacemaker in this patient population include aortic insufficiency, pulmonary hypertension, and prior MI. The incidence of AV block is doubled when aortic valve surgery is combined with mitral valve or coronary bypass surgery.³⁴

The overall rate of requirement of a permanent pacemaker is significantly higher (more than 17%) after transcatheter aortic valve replacement (TAVR). Several parameters indicate a high risk of requirement of a permanent pacemaker post TAVR, including male sex, pre-existing AV conduction abnormalities (including first-degree AV delay, LAF block, and RBBB), and intraprocedural AV block. In addition, the risk of pacemaker implantation is 2.5-fold higher in patients receiving the Medtronic CoreValve Revalving System (Medtronic, Minneapolis,

MN) than in those receiving the balloon-expandable Edwards SAPIEN valve (Edwards Lifesciences, Irvine, CA, United States; 19% to 42% vs. 7% to 22%). This is likely related to the valve design (self-expanding vs. balloon-expandable) and the potential of a deeper implantation into the left ventricular outflow tract, causing more injury to the AVN and left bundle branches, which may be delayed because of the self-expanding nature of the prosthesis and tissue edema. Other reported risk factors include advanced age, permanent AF, preoperative bradycardia, larger or oversized prosthesis, and postprocedural new-onset of LBBB.^{35,36}

New LBBB is the most common conduction abnormality observed after TAVR, occurring in 29% to 65% with the Medtronic CoreValve and in 6% to 30% with Edwards SAPIEN valve. It usually occurs during the procedure but can develop afterward in 2% to 8% of patients.³⁷ Although new-onset LBBB after TAVR can be transient and disappears within the first few days in 19% to 34% of patients, it persists in the majority of patients. The risk of progression from LBBB to complete AVB is relatively high. Furthermore, LBBB appears to be an independent predictor of all-cause mortality at 1 year. In the subgroup of patients with new-onset LBBB, the HV interval after TAVR was found to predict AV block with a reasonable diagnostic accuracy.^{35,36} However, whether the development of new LBBB without AV block warrants electrophysiological (EP) testing or prophylactic pacemaker implantation has not yet been validated.^{35,38,39}

Other Causes of Atrioventricular Block

AV block can also occur in a variety of other disorders including hyperkalemia, hypermagnesemia, hyperthyroidism, myxedema, and Addison disease.

Paroxysmal Atrioventricular Block

Three forms of paroxysmal AV block have been described: vagally mediated AV block, intrinsic AV block, and idiopathic AV block.^{40,41,42}

Paroxysmal Vagally Mediated Atrioventricular Block

Vagally mediated AV block is a paroxysmal form of AV block induced by surges of vagal discharge. It occurs in patients with or without heart disease, most of them with no prior evidence of AV or intraventricular

conduction abnormalities. AV block is localized within the AVN, is associated with a narrow QRS escape rhythm, and is generally benign.

The prevalence of vagally mediated AV block is unknown. Not infrequently, it is accidentally encountered as an asymptomatic event during cardiac monitoring, occurring more often during the night (commonly, but not always, precipitated by nocturnal apnea), and in most cases without ventricular asystole. However, prolonged ventricular pauses are common during syncope, typically preceded by identifiable triggering and predisposing factors suggesting a diagnosis of reflex syncope, such as vomiting, coughing, micturition, or phlebotomy, among others. In addition, transient AV block (Wenckebach, 2:1, high grade, or complete AV block) can occur secondary to enhanced vagal tone caused by hypersensitive carotid sinus syndrome and neurocardiogenic syncope. However, the cause of the vagal surge may not be evident in some patients.⁴⁰ Often, the episodes of syncope are preceded by a prodrome of symptoms of vagotonia (lightheadedness, diaphoresis, warm clammy feeling, and nausea). However, some patients experience no such warnings.

A classic vagal effect on the conduction system includes gradual slowing of the sinus rate (P-P interval) and AV conduction (first-degree or Wenckebach block), due to simultaneous vagal effect on both the sinus node and AVN, occasionally followed by sinus arrest or complete AV block. Not infrequently, a more prominent AV response with sudden AV block can occur with heightened vagal tone; nevertheless, slowing of the sinus rate and prolongation of PR interval in at least one beat typically precedes complete AV block. The sinus rate continues to slow down during ventricular asystole. This is followed by gradual resumption of AV conduction (with initial significant PR interval prolongation) and sinus acceleration.

Paroxysmal Intrinsic Atrioventricular Block

Paroxysmal intrinsic AV block is characterized by pause-dependent, abrupt, and sustained AV block occurring in diseased HPS. The change from apparently normal 1:1 AV conduction to complete heart block is sudden and unexpected. The block is usually initiated by conducted or nonconducted premature atrial complexes (PACs) or premature ventricular contractions (PVCs) or by a change of baseline heart rate, and it persists until another PAC or PVC or rate change terminates it (Fig. 9.3). Episodes of AV block are commonly associated with prolonged

Fig. 9.3 Paroxysmal Intrinsic Atrioventricular Block. Shown are two-channel rhythm strips during sinus rhythm with prolonged but stable PR interval and right bundle branch block. A premature ventricular complex (middle, top panel) occurs and is followed by a string of nonconducted P waves for almost 10 seconds until conduction resumes (at a faster sinus rate and with slightly shorter PR intervals, likely because of sympathetic discharge during the asystole).

periods of ventricular asystole (of unpredictable duration) precipitating presyncope or syncope and potentially sudden death. Long-term outcome is characterized by a rapid progression toward permanent AV block.^{43,44}

Paroxysmal AV block is a rare, unique disorder of the HPS, possibly caused by local phase 4 block in the HPS after a critical change in the H-H interval (see Chapter 10). Phase 4 or diastolic depolarization is a property of pacemaker cells of the heart; normal His-Purkinje fibers do not possess this property. However, diseased Purkinje cells can manifest phase 4 depolarization. During a long pause (prolonged diastolic period), the fibers of the often-diseased HPS spontaneously depolarize (membrane potential becomes less negative) and become less responsive to subsequent impulses due to Na⁺ channel inactivation. The critical prolongation of the input stimulus is typically initiated by a compensatory pause after a PAC or PVC, spontaneous slowing of the sinus rate, or overdrive suppression of sinus rhythm on termination of a fast supraventricular rhythm. Once a critical diastolic membrane potential is reached (at which sodium channel inactivation occurs), subsequent conduction may not resume until a well-timed escape beat or premature beat (sinus or ectopic) resets the transmembrane potential to its excitable state. It is important to note that, in some cases, pause-dependent block may be caused by other mechanisms (e.g., source-to-sink mismatch) that may not be related to phase 4 depolarization.^{43,44,45}

No specific or optimal tests exist to diagnose paroxysmal AV block. Patients with paroxysmal intrinsic AV block may or may not have structural heart disease at baseline, and conduction abnormalities may not be evident on resting electrocardiograms (ECGs), and when present, RBBB is the most common finding. The role of EP testing remains uncertain because there is no predictable marker for identifying patients at risk for paroxysmal AV block. Although paroxysmal AV block may be reproduced during EP testing via critically timed atrial or ventricular extrastimuli, a negative EP study result does not exclude the diagnosis of paroxysmal AV block.

Paroxysmal Idiopathic Atrioventricular Block

Paroxysmal “idiopathic” AV block is a recently described distinct form of paroxysmal AV block in patients with recurrent syncope. This form of AV block is unexplainable in terms of currently known mechanisms and has clinical and EP features distinct from those of the two other known types of paroxysmal AV block: intrinsic AV block due to AV conduction disease and extrinsic vagal AV block.⁴¹

Idiopathic paroxysmal AV block is characterized sudden onset of complete AV block causing one or multiple consecutive asystolic pauses and recurrent syncope, absence of cardiac and resting ECG abnormalities, and absence of progression to persistent forms of AV

block (Fig. 9.4). AV block occurs without P-P cycle lengthening or PR interval prolongation (unlike paroxysmal vagal AV block) and is not triggered by PACs or PVCs or by variations in the baseline heart rate (unlike paroxysmal intrinsic AV block).⁴¹

The mechanism of idiopathic AV block has not been elucidated yet. A possible role of adenosine has been suggested. Patients with this form of AV block have low baseline adenosine plasma level values as compared with controls or to patients with reflex (vagal) asystolic syncope. Furthermore, patients with idiopathic AV block frequently exhibit an increased susceptibility to exogenous adenosine; the rapid intravenous injection of 18 mg adenosine or 20 mg adenosine triphosphate (ATP) reproduced spontaneous AV block in the majority of patients. The adenosine response could be abolished by theophylline (an adenosine antagonist) but not by atropine (a vagal antagonist). However, the adenosine test does not appear to be specific, and its value in clinical practice requires further evaluation. Carotid sinus massage or tilt table testing did not reproduce AV block. Permanent pacing was successful in preventing syncopal recurrences during long-term follow-up in patients with idiopathic AV block.^{41,45,46}

Distinction between the three forms of paroxysmal AV block (vagally mediated, intrinsic, and idiopathic) has important prognostic and therapeutic implications. Table 9.1 lists features of each entity, although some of those characteristics can have limited sensitivity and/or specificity, as discussed previously.^{41,42}

CLINICAL PRESENTATION

Symptoms in patients with AV conduction abnormalities are generally caused by bradycardia and loss of AV synchrony. Symptoms caused by advanced AV block can range from exercise intolerance, easy fatigability, dyspnea on exertion, angina, mental status changes, dizziness, and near syncope to frank syncope. In patients with paroxysmal or intermittent complete heart block, symptoms are episodic, and routine ECGs may not be diagnostic. Importantly, acquired AV block can lead to prolongation of the QT interval and torsades de pointes, a potentially lethal complication.⁴⁷

Individuals with first-degree AV delay are usually asymptomatic; however, marked prolongation of the PR interval (longer than 300 milliseconds) can precipitate symptoms similar to those with pacemaker syndrome caused by loss of AV synchrony and atrial contraction against closed AV valves.⁴⁸ In addition, in patients with LV dysfunction, severe first-degree AV delay can lead to impaired hemodynamics, “diastolic” mitral regurgitation, and reduction in cardiac output, with consequent worsening of heart failure symptoms.⁴⁹

TABLE 9.1 Differential Diagnosis of Paroxysmal Atrioventricular Block			
	Paroxysmal Vagally Mediated AV Block	Paroxysmal Intrinsic AV Block	Paroxysmal Idiopathic AV Block
Triggers	Heightened vagal tone	PAC, PVC, change in heart rate	No identifiable triggers
Sinus rate before/during AVB	Slowing	Accelerating	Accelerating
First-degree and/or Wenckebach AV block before or after complete AV block	Common	Absent	Absent
Wide QRS	Uncommon	Common	Common
Level of block	AVN	HPS	HPS
Adenosine plasma level	High	Normal	Low
Sensitivity to Adenosine	Uncommon	Uncommon	Common
Response to pacing therapy	Modest	Good	Good

AV, Atrioventricular; AVB, atrioventricular block; AVN, atrioventricular node; HPS, His-Purkinje system; PAC, premature atrial complexes; PVC, premature ventricular contractions.

Fig. 9.4 Paroxysmal Idiopathic Atrioventricular Block. Implantable loop recorder documentation of syncope due to idiopathic atrioventricular (AV) block. (A) Heart rate trend during 4-minute loop recording. Initially, the heart rate is stable at 60 beats/min and suddenly falls at the time of syncope. (B) Expanded electrocardiogram. The five strips are continuous and show a blocked P wave followed by a complete AV block with an asystolic pause of 20 seconds. During AV block, the P-P cycle is initially constant and then progressively shortens, indicating compensatory reflex sympathetic activation. There is no apparent trigger of the onset of AV block. (From Brignole M, Guieu R, Tomaino M, et al. Mechanism of syncope without prodromes with normal heart and normal electrocardiogram. *Heart Rhythm*. 2016;14:234–239.)

On physical examination, the “a” to “c” wave interval in the jugular venous pulse prolongs and intensity of the first heart sound diminishes as the PR interval lengthens. These changes can be constant in first-degree AV delay, or dynamic, mirroring the changes in PR interval in type I second-degree AV block. In the latter setting, the “a” wave is intermittently not followed by “v” wave, indicating failure of conduction of the P wave to the ventricles. Wenckebach used an analysis of the jugular venous pulse to first describe the phenomenon of type I second-degree AV block.

Congenital AV block can be apparent in utero or at birth; however, many individuals have few or no symptoms and reach their teens or young adulthood before the diagnosis is made. Because of the presence of reliable subsidiary HB pacemakers with adequate rates (especially in the presence of catecholamines), syncope is rare with congenital complete AVN block. Some patients become symptomatic only when aging produces chronotropic incompetence of the escape rhythm.

NATURAL HISTORY

The natural history of patients with AV block depends on the underlying cardiac condition. In addition, the site of the block and the resulting rhythm disturbances themselves contribute to the prognosis. Healthy middle-aged subjects with first-degree AV delay have an excellent prognosis, even when associated with chronic bifascicular block, because the rate of progression to third-degree AV block is low. However, in older populations and in patients with underlying heart failure or coronary artery disease, prolongation of the PR interval was found to be an adverse prognostic marker and a predictor of higher risk of AF and heart failure.⁴⁹

Type 1 second-degree AV block is generally benign; however, when type 1 AV block occurs in association with bifascicular block, the risk of progression to complete heart block is significantly increased because of probable infranodal site of AV conduction delay. Type 2 second-degree

Fig. 9.5 Improvement of Atrioventricular (AV) Conduction With Carotid Sinus Pressure. Two ECG leads are shown in a patient with right bundle branch block, left axis deviation and 2:1 AV block. Carotid sinus pressure is applied (red arrow), P-P intervals shown at bottom gradual increase following this, allowing adequate time for His-Purkinje refractoriness to recover and restore 1:1 AV conduction (at right).

AV block carries a high risk of progression to advanced or complete AV block, which can occur suddenly. The prognosis of 2:1 AV block depends on whether the site of block is within or below the AVN.

The prognosis for patients with symptomatic acquired complete heart block is poor in the absence of pacing, regardless of the extent of the underlying heart disease. However, once appropriate pacing therapy has been established, the prognosis depends on the underlying disease process. As noted previously, high-degree AV block complicating acute MI is associated with high in-hospital and 30-day mortality but has no impact on 1-year mortality among 30-day survivors.^{19,20} In contrast, complete heart block secondary to idiopathic fibrosis of the conduction system in the absence of additional cardiac disease carries a more benign prognosis. AV block after valve surgery can recover; however, if conduction has not recovered by 48 hours after surgery, permanent pacing will likely be necessary.

Congenital complete AVB diagnosed in utero or at birth is associated with an approximately 30% mortality rate in utero or in the early postnatal life. Mortality is much lower during childhood and adolescence and increases slowly later in life. Many patients have few or no symptoms and reach their teens or young adulthood before the diagnosis is made. The outlook for patients with congenital heart block depends largely on the presence or absence of underlying structural heart disease. Patients with concomitant structural heart disease, a wide QRS complex, or LQTS are more likely to develop symptoms early and are at an increased risk for sudden death. Of all cases that have been recognized with congenital heart block, approximately two-thirds will have a pacemaker placed before reaching adulthood.^{10,12}

DIAGNOSTIC EVALUATION

Because the prognosis and, in some cases, the treatment of AV block differ depending on whether the block is within the AVN or is infranodal, determining the site of block is important. In most cases, this can be achieved noninvasively.

Electrocardiography

The QRS duration, PR interval, and ventricular rate on the surface ECG can provide important clues for localizing the level of AV block (see later).

Autonomic Modulation

Although the AVN is richly innervated and highly responsive to both sympathetic and vagal stimuli, the HPS is influenced less so by the autonomic nervous system. Carotid sinus massage increases vagal tone and worsens second-degree AVN block, whereas exercise and atropine

improve AVN conduction because of sympathetic stimulation or parasympathetic withdrawal. In contrast, carotid sinus massage can improve second-degree infranodal block by slowing the sinus rate and allowing HPS refractoriness to recover (Fig. 9.5). In addition, exercise and atropine worsen infranodal block because of the enhanced function of the sinus node and AVN and, as a consequence, the increased rate of impulses conducted to the HPS without changing HPS refractoriness.

Exercise Testing

Vagolysis and increased sympathetic drive that occur with exercise enhance AVN conduction. Thus patients with first-degree AV delay can have shorter PR intervals during exercise, and patients with type 1 second-degree AV block can develop higher AV conduction ratios (e.g., 3:2 at rest becoming 6:5 during exercise).

Exercise testing can be a useful tool to help confirm the level of block in second- or third-degree AV block associated with a narrow or wide QRS complex. Patients with presumed type 1 block or congenital complete heart block and a normal QRS complex usually have an increased ventricular rate with exercise, the former because of improved AVN conduction and the latter because of a faster escape rate. On the other hand, patients with acquired complete heart block and a wide QRS complex usually show minimal or no increase in ventricular rate. In addition, patients with 2:1 AV block in whom the site of conduction block is uncertain can benefit from exercise testing by observing whether the AV conduction ratio increases in a Wenckebach-like manner (e.g., to 3:2 or 4:3) or decreases (e.g., to 3:1 or 4:1). In the latter setting the increase in the sinus rate finds the HPS refractory, thus causing the higher degrees of block. This response is always abnormal, and it indicates intra-Hisian or infra-Hisian block, which requires permanent cardiac pacing.

Electrophysiological Testing

EP testing is usually not required for the diagnosis or treatment of AV block, because the previously described noninvasive measures are usually adequate. Nevertheless, EP testing can be of value in symptomatic patients in whom AV conduction abnormalities are suspected but cannot be documented or in patients with equivocal ECG findings.

ELECTROCARDIOGRAPHIC FEATURES

First-Degree Atrioventricular Delay

First-degree AV delay manifests on the surface ECG as a PR interval longer than 200 milliseconds following a normally timed (nonprematuring) P wave. All P waves are conducted but with delay; each P wave is followed by a QRS complex with a constant, prolonged PR interval.

Fig. 9.6 First-Degree Atrioventricular Delay Caused by Intranodal Conduction Delay. The intranodal conduction delay is indicated by the prolonged atrial–His bundle (AH) and normal pulmonary artery and His bundle–ventricular (HV) intervals. *CS_{dist}*, Distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

Fig. 9.7 First-Degree Atrioventricular Delay Secondary to His-Purkinje System Disease. The atrial–His bundle (AH) interval is normal but the His bundle–ventricular (HV) interval is markedly prolonged and associated with complete left bundle branch block. *His_{mid}*, Middle His bundle; *His_{prox}*, proximal His bundle; *His_{wide}*, wide His bundle; *HRA*, high right atrium; *RV*, right ventricle.

Site of Block

The degree of PR interval prolongation and QRS duration can help predict the site of conduction delay. Very long (more than 300 milliseconds) or highly variable PR intervals suggest involvement of the AVN. Normal QRS duration also suggests involvement of the AVN.

Atrioventricular node. Although conduction delay can be anywhere along the AVN–HPS, the AVN is the most common site of delay (87% when the QRS complex is narrow, and more than 90% when the PR interval is longer than 300 milliseconds; Fig. 9.6).

His-Purkinje system. Intra-Hisian conduction delay or HPS disease can cause prolongation of the PR interval. First-degree AV delay in the presence of BBB is caused by infranodal conduction delay in 45% of cases. A combination of delay within the AVN and in the HPS must also be considered (Fig. 9.7).

Atrium. Not infrequently, first-degree AV delay is caused by intraatrial or interatrial conduction delay. RA enlargement can prolong the PR interval (eFig. 9.1), as can be observed in certain cases of congenital structural heart disease, such as Ebstein anomaly of the tricuspid valve or endocardial cushion defects, or after surgical repair of congenital disease (e.g., Fontan repair of single ventricle, Mustard/Senning repairs of transposed great arteries). The presence of LA enlargement pattern on the ECG (i.e., prolonged P wave duration) reflects the presence of interatrial conduction delay and can be a clue to the underlying mechanism of first-degree AV delay.⁵⁰

Second-Degree Atrioventricular Block

The term second-degree AV block is applied when intermittent failure of AV conduction is present (i.e., one or more atrial impulses that should be conducted fail to reach the ventricles). This term encompasses several conduction patterns. Types 1 and 2 AV block are ECG patterns that describe the behavior of the PR intervals (in sinus rhythm) in sequences (with at least two consecutively conducted PR intervals) in which a single P wave fails to conduct to the ventricles. The anatomical site of block should not be characterized as either type 1 or type 2 because these designations refer only to ECG patterns.⁵¹

Type 1 Second-Degree Atrioventricular Block

Type 1 second-degree AV block (Wenckebach or Mobitz type I block) manifests on the surface ECG as progressive prolongation of the PR interval before failure of an atrial impulse to conduct to the ventricles. The PR interval immediately after the nonconducted P wave returns to its baseline value, and the sequence begins again.

The behavior of Wenckebach block can be simplified by relating it to an abnormally long relative refractory period of the AVN. In this setting the rate of AVN conduction depends on the time that the impulse arrives at the AVN. The earlier it arrives at the AVN, the longer it takes to propagate through the AVN, and the longer the PR interval will be; the later it arrives, the shorter the conduction time, and the shorter the PR interval. Thus Wenckebach periodicity in part develops because each successive atrial impulse arrives earlier and earlier in the relative refractory period of the AVN, thus resulting in longer and longer conduction delay and PR interval, until one impulse arrives during the absolute refractory period and fails to conduct, with a consequent ventricular pause. In other words, the shorter the RP interval is, the longer the PR interval will be; and the longer the RP interval is, the shorter the PR interval will be; they are inversely related. This is referred to as RP-PR reciprocity or RP-dependent PR interval. Using this concept, it is easy to explain the behavior of the PR interval during the Wenckebach periodicity. The first atrial impulse conducting after the pause has an unusually long RP interval, whereas with the following atrial impulse, the RP interval dramatically shortens, thus resulting in prolongation of the PR interval. Although the following atrial impulses have shorter RP intervals, such shortening is not as dramatic, and consequently the progressive prolongation of the PR interval is of lesser degree. In other words, although each successive PR interval prolongs, it does so at a decreasing increment. So, for example, if the PR interval following the first conducted P wave in the cycle increased by 100 milliseconds, the PR interval of the next beat would increase by 50 milliseconds, and so forth.

Features of typical Wenckebach periodicity include the following: (1) progressive lengthening of the PR interval throughout the Wenckebach

eFig. 9.1 First-Degree Atrioventricular Delay Caused by Intraatrial Conduction Delay. The long PR interval (240 milliseconds) is caused by prolonged conduction in the right atrium (prolonged PA interval) in a patient who has undergone Fontan repair for complex congenital heart disease. *CS_{dist}*, Distal coronary sinus; *His_{dist}*, distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *Low-Lat RA*, low lateral right atrium; *Low-Med RA*, low medial right atrium; *Mid-Lat RA*, middle lateral right atrium.

cycle; (2) lengthening of the PR interval occurring at progressively decreasing increments, resulting in progressively shorter R-R intervals; (3) a pause between QRS complexes encompassing the nonconducted P wave that is less than the sum of R-R intervals of any two consecutively conducted beats; (4) shortening of the PR interval after block, compared with the PR interval just preceding the blocked cycle; and (5) group beating, which offers a footprint that identifies Wenckebach periodicity (eFig. 9.2). It is important to recognize that, during Wenckebach periodicity, the atrial impulse conducted to the ventricles is not always represented by the P wave that immediately precedes the QRS complex; the PR interval can be very long and exceed the P-P interval.

However, less than 50% of type 1 AV block cases follow this typical pattern. Typical Wenckebach periodicity is more frequently observed during pacing-induced AV block. Atypical patterns are more likely found with longer Wenckebach periods (more than 6:5 atrial/ventricular complexes). In patients with dual AVN physiology, Wenckebach cycles are almost always atypical; the greatest increment in the atrial–His bundle (AH) interval occurs when block occurs in the fast pathway, whichever beat this may be. Differentiating atypical from typical patterns is of

little clinical significance. However, an atypical pattern can be misdiagnosed as type 2 second-degree AV block. Some possible atypical features of Wenckebach periodicity include the following: (1) the second (conducted) PR interval (after the pause) often fails to show the greatest increment, and the increment may actually increase for the PR interval of the last conducted beat in the cycle (Fig. 9.8); (2) very little incremental conduction delay and no discernible change in the duration of the PR intervals for a few beats just before termination of a sequence (this is seen most often during long Wenckebach cycles and in association with increased vagal tone and is usually accompanied by slowing of the sinus rate; Fig. 9.9); (3) the PR interval can actually shorten and then lengthen in the middle of a Wenckebach sequence; and (4) a junctional escape beat can end the pause following a nonconducted P wave, resulting in an apparent shortening of the PR interval.

AVN block usually can be reversed completely or partially by altering the autonomic tone (e.g., with atropine). However, these measures fail occasionally, especially in the presence of structural damage to the AVN (e.g., congenital heart disease or inferior wall MI). In such cases, progression to complete AV block can occur, although such an event is more likely to occur with block in the HPS.

Fig. 9.8 Atypical Wenckebach Periodicity Due to Increased Vagal Tone. Type 1 second-degree atrioventricular (AV) block caused by heightened vagal tone. Note the greatest increment occurs in the PR interval of the last conducted beat in the cycle and not in the second PR interval after the pause. Also note the slowing in the sinus rate coinciding with significant prolongation in the PR interval and then AV block, a finding suggesting that increased vagal tone is responsible for both slowing of the sinus rate and atrioventricular nodal block. HRA, High right atrium.

Fig. 9.9 Atypical Wenckebach Periodicity. Note the very small increments in the duration of the PR intervals for a few beats just before termination of a sequence. However, the first conducted P wave after the pause is associated with obvious shortening of the PR interval.

eFig. 9.2 Typical Wenckebach Periodicity. Normal sinus rhythm with type 1 second-degree atrioventricular block is characterized by progressive prolongation of the PR intervals preceding the nonconducted P wave and group beating.

Fig. 9.10 Intranodal Second-Degree Atrioventricular Block. Normal sinus rhythm with type 1 second-degree atrioventricular (AV) block is characterized by progressive prolongation of the PR intervals preceding the nonconducted P wave and group beating. Despite the presence of His-Purkinje system disease (as indicated by incomplete right bundle branch block), Wenckebach AV block is more common in the atrioventricular node. At right, the last four P waves encountered 2:1 AV block.

Site of block. The degree of PR interval prolongation and QRS duration can help to predict the site of block. A normal QRS duration usually suggests AVN involvement, whereas the presence of BBB suggests (but does not prove) HPS involvement. Furthermore, a short baseline PR interval and small PR interval increments preceding the block suggest HPS involvement.

Atrioventricular node. Wenckebach block is almost always within the AVN (and rarely intra-Hisian) when a narrow QRS complex is present.

His-Purkinje system. When type 1 block is seen with the presence of BBB, the block is still more likely to be in the AVN (Fig. 9.10), but it can also be localized within or below the HB (Fig. 9.11). In this setting a very long PR interval is more consistent with AVN block.

Type 2 Second-Degree Atrioventricular Block

Type 2 second-degree (Mobitz type II) AV block is characterized on the surface ECG by a constant (normal or prolonged) PR interval of all conducted P waves, followed by sudden failure of a P wave to be conducted to the ventricles (eFig. 9.3). RP-PR reciprocity, the hallmark of type 1 block, is absent in type 2 block. Consequently, the PR interval following a long RP interval (immediately following the pause) is identical to that following a short RP interval (immediately preceding the pause). Type 2 block cannot be diagnosed if the first P wave after a blocked beat is absent or if the PR interval following the pause is shorter than all the other PR intervals of the conducted P waves, regardless of the number of constant PR intervals before the block (see Fig. 9.9). The P-P intervals remain constant, and the

Fig. 9.11 Infra-Hisian Second-Degree Wenckebach Atrioventricular Block. Atrial pacing in a patient with a normal prolonged atrial-His bundle interval but prolonged His bundle-ventricular (HV) interval and right bundle branch block (RBBB). On the second complex, the HV is dramatically prolonged and left bundle branch block is present, suggesting very slow conduction over the right bundle branch. With the third paced complex, atrioventricular block occurs below the His bundle recording, and on the fourth complex, conduction with RBBB resumes, suggesting a Wenckebach cycle in the His-Purkinje system. *His_{prox}*, proximal His bundle; *RVA*, right ventricular apex.

pause encompassing the nonconducted P wave equals twice the P-P interval.⁵¹

A true Mobitz type II AV block in conjunction with a narrow QRS complex is relatively rare and occurs without sinus slowing and without the characteristic Wenckebach sequences. Atypical forms of

eFig. 9.3 Second-Degree Intra-Hisian Atrioventricular Block. Despite the presence of narrow QRS complexes, the site of block is likely intra-Hisian, as suggested by the short PR intervals on conducted beats and no increment in the PR intervals on 3:2 cycles. The P waves frequently are partially concealed within the preceding T waves (especially in view of the presence of long QT intervals) and are more obvious in lead V3. Note QRS aberrancy (right bundle branch block) resulting from the long-short R-R intervals.

Wenckebach block with only minimal PR interval variation should be excluded (see Fig. 9.9). Apparent type 2 second-degree AV block can be observed not infrequently under the influence of increased vagal tone during sleep, in which case Wenckebach block without discernible or measurable increments in the PR intervals is the actual diagnosis; sinus slowing with AV block essentially excludes Mobitz type II block. When an apparent Mobitz type II-like pattern with a narrow QRS complex alternating with periods of intermittent Wenckebach AV block sequences (as in Holter recordings), a true Mobitz type II block can be safely excluded because narrow QRS type 1 and type 2 second-degree AV blocks almost never coexist within the HB. On the other hand, sustained advanced second-degree AV block is far more common in association with true Mobitz type II block than with Wenckebach block or its variant.

Apparent Mobitz type II AV block can also be caused by concealed junctional extrasystoles (confined to the specialized conduction system

and not propagated to the myocardium) and junctional parasystole (Fig. 9.12).⁵² Exercise-induced second-degree AV block is most commonly infranodal and rarely is secondary to AVN disease or myocardial ischemia.

Site of block

His-Purkinje system. Type 2 second-degree AV block is almost always below the AVN, occurring in the HB in approximately 30% of cases and in the bundle branches in the remainder (Fig. 9.13). Infrequently, type 2 second-degree AV block is found with a narrow QRS complex and is caused by intra-Hisian block (see eFig. 9.3).

Atrioventricular node. Type 2 second-degree AV block has not yet been convincingly demonstrated in the body of the AVN or the N zone. Although multiple reports have described the occurrence of type 2 second-degree AV block in the AVN, in each case either the block could have been localized to the HPS, rather than the AVN, or the block probably was an atypical variant of Wenckebach block.

Fig. 9.12 Junctional Ectopy Mimicking Mobitz Type II Atrioventricular Block. The lead II rhythm strip shows sinus rhythm with normal atrioventricular conduction, but the second complex (*black arrow*) is a normal QRS not preceded by a P wave (thus His bundle extrasystole) with retrograde conduction (inverted P wave following QRS). The white arrow shows a nonconducted P wave that would ordinarily indicate Mobitz II block, but in this patient with known His bundle (junctional) extrasystoles, the P wave more likely fails to conduct because of concealed conduction into the atrioventricular node following a concealed His extrasystole (no resultant QRS or retrograde P wave). Note that the nonconducted P wave has a slightly different contour, perhaps as a result of fusion between the sinus P wave and retrograde atrial capture from the concealed His bundle extrasystole.

Fig. 9.13 Type II Second-Degree Infranodal Atrioventricular Block. Bifascicular block (right bundle branch block and left anterior fascicular block) and normal, constant PR intervals (196 milliseconds) are observed during conducted beats, consistent with infranodal block.

Second-Degree 2:1 Atrioventricular Block

When only alternate beats are conducted, resulting in a 2:1 ratio, the PR interval is constant for the conducted beats, provided that the atrial rhythm is regular (Fig. 9.14). A 2:1 AV block cannot be classified as type 1 or type 2; using the term type 1 to describe 2:1 AV block when the lesion is in the AVN or when there is evidence of decremental conduction and using the term type 2 to describe 2:1 AV block when it is infranodal or when there is evidence of all-or-none conduction should be discouraged because this practice violates the well-accepted traditional definitions of types 1 and 2 block based on ECG patterns,

not on the anatomical site of block. Both types 1 and 2 block can progress to a 2:1 AV block, and a 2:1 AV block can regress to type 1 or 2 block.⁵¹

Site of block. Fixed 2:1 AV block poses a diagnostic dilemma because it can be difficult to localize the site of block by the surface ECG alone. Several ECG features can help in the differential diagnosis:

1. A 2:1 AV block associated with a narrow QRS complex is likely to be intranodal, whereas that associated with a wide QRS complex is likely to be infranodal, but it could still be at the level of the AVN (Figs. 9.14 and 9.15).

Fig. 9.14 Second-Degree Atrioventricular (AV) Block. Normal sinus rhythm with second-degree 2:1 AV block. At right, the conduction pattern changes from 2:1 AV block pattern to a Wenckebach pattern.

Fig. 9.15 Second-Degree 2:1 Infranodal Atrioventricular Block. Note the short PR interval during conducted complexes and the wide QRS complexes (right bundle branch block), suggesting block in the His-Purkinje system.

2. Fixed 2:1 AV block with PR intervals shorter than 160 milliseconds suggests intra-Hisian or infra-Hisian block, whereas very long PR intervals (more than 300 milliseconds) suggest AVN block.
3. If the PR interval of all the conducted complexes is constant despite a varying RP interval, infranodal block is likely.
4. The presence of Wenckebach block before or after episodes of 2:1 AV block is highly suggestive of block at the AVN level (see Figs. 9.10 and 9.14).
5. Improvement of block with atropine or exercise suggests AVN block; however, the absence of such response does not exclude intranodal block.

High-Grade Atrioventricular Block

Failure of conduction of two or more consecutive P waves when AV synchrony is otherwise maintained is sometimes termed high-grade AV block or advanced second-degree AV block (Fig. 9.16). This block must happen because of the existing block itself and not because of retrograde concealment in the AVN or HPS resulting from junctional or ventricular escape complexes that prevent conduction.

Site of block. The level of block can be at the AVN or the HPS. When high-degree AV block is caused by block in the AVN, QRS complexes of the conducted beats are usually narrow. Wenckebach periodicity can also be seen, and atropine administration produces lesser degrees of AV block. Features suggesting block in the HPS are conducted beats with BBB and no improvement in block with atropine.

Third-Degree (Complete) Atrioventricular Block

AV block is termed complete when all P waves fail to conduct, despite having ample opportunity for conduction. Therefore, if there is less than optimal opportunity for the AVN-HPS to conduct (e.g., a ventricular escape rate exceeding 40/min), it cannot be regarded as complete

AV block if a P wave does not conduct. Third-degree AV block is seen on the surface ECG as completely dissociated P waves and QRS complexes, each firing at its own pacemaker rate, with a continuously changing PR relationship as the P waves march through all phases of the ventricular cycle in the presence of a regular ventricular rhythm (Fig. 9.17). Every possible chance for conduction is afforded, with the P waves occurring at every conceivable RP interval, but the atrial impulse is never conducted to the ventricles. The atrial rate is always faster than the ventricular rate (Fig. 9.18).

Site of Block

Atrioventricular node. Most cases of congenital third-degree AV block are localized to the AVN (see Fig. 9.17), as are cases of transient AV block associated with acute inferior wall MI, beta blockers, calcium channel blockers, and digitalis toxicity. Complete AVN block is characterized by a junctional escape rhythm with a narrow QRS complex and a rate of 40 to 60 beats/min, which tends to increase with exercise or atropine. However, in 20% to 50% of patients with chronic AV block, a wide QRS escape rhythm may occur. Rhythms originating in the distal HB may have a wide QRS. Those rhythms are usually slower and non-responsive to atropine.

His-Purkinje system. Acquired complete heart block is usually associated with block in the HPS that results in an escape rhythm with a wide QRS complex with a rate of 20 to 40 beats/min (Fig. 9.19).

ELECTROPHYSIOLOGICAL TESTING

Role of Electrophysiological Testing

ECG diagnosis of AV block is usually adequate for deciding subsequent treatment. Once symptoms and AV block are correlated with ECG findings, further documentation by invasive studies is not required unless

Fig. 9.16 High-Grade Atrioventricular Block. Note that only three P waves conducted to the ventricle in the whole tracing. Conducted P waves were associated with normal PR intervals and right bundle branch block, a finding suggesting infranodal block. All other P waves were blocked, and ventricular escape rhythm with a left bundle branch block pattern is observed. Note that the block is not caused by retrograde concealment in the atrioventricular node or His-Purkinje system from the ventricular escape complexes because the conducted P waves occurred at a short cycle following the escape complexes.

Fig. 9.17 Congenital Third-Degree Atrioventricular Block. Sinus rhythm with complete atrioventricular block and junctional escape rhythm with a narrow QRS are seen, consistent with intranodal block.

Fig. 9.18 Competing Sinus and Junctional Rhythms Mimicking Atrioventricular (AV) Block. Surface ECG of sinus bradycardia at a cycle length (CL) of 1180 milliseconds and junctional escape rhythm at a shorter CL (1080 milliseconds). Junctional impulses fail to conduct retrogradely to the atrium, thus setting the stage for AV dissociation, which is observed during most of the recording. Note that no pathological AV block is present; failure of AV conduction of several sinus impulses occurred secondary to the physiological refractoriness of the atrioventricular node (AVN) and His bundle (HB) caused by retrograde concealment by the escape junctional impulses. However, whenever sinus P waves occurred at appropriate timings, they did conduct to the ventricle (red and green arrows) and elicited QRS complexes at CLs shorter than the expected junctional rhythm CL. Note that retrograde concealment of the junctional impulses occurred in the AVN and not just the HB, evident by the prolonged PR intervals of conducted sinus P waves when they closely follow the preceding QRS complex (green arrows). Numbers denote R-R intervals in milliseconds.

Fig. 9.19 Complete Infranodal Atrioventricular Block. Complete atrioventricular dissociation is observed, and all the P waves fail to conduct despite having ample opportunity for conduction. Note the slow ventricular escape rhythm with a wide QRS complex and a rate of 40 beats/min, consistent with block in the His-Purkinje system.

additional information is needed. Similarly, asymptomatic patients with transient Wenckebach block associated with increased vagal tone should not undergo EP testing.

Nevertheless, EP testing can help diagnose an equivocal ECG pattern or delineate the site of conduction abnormality, if that is required for therapeutic decision making. EP testing is indicated in a patient with suspected high-grade AV block as the cause of syncope or presyncope when documentation cannot be obtained noninvasively. Similarly, in patients with coronary artery disease, it can be unclear whether symptoms are secondary to AV block or VT; therefore EP testing can be useful in establishing the diagnosis. Some patients with known second- or third-degree block can benefit from an invasive study to localize the site of AV block to help determine therapy or assess prognosis.

Normal Atrioventricular Conduction

The normal PR interval is 120 to 200 milliseconds. This interval reflects the conduction time from the high RA to the point of earliest ventricular activation (i.e., QRS onset), and it includes activation of the atrium, AVN, HB, bundle branches and fascicles, and terminal Purkinje fibers. To measure the different components of the conduction system contained in the PR interval, intracardiac recordings from the high RA and HB region are required.

The PA interval, measured from the high RA electrogram to the low RA deflection in the HB recording, gives an indirect approximation of the intraatrial conduction time. The normal PA interval is 20 to 60 milliseconds.

The AH interval is measured from the first rapid deflection of the atrial deflection in the HB recording to the first evidence of HB depolarization in the HB recording. The AH interval is an approximation of AVN conduction time because it represents conduction time from the low RA at the interatrial septum through the AVN to the HB. The AH interval has a wide range in normal subjects (50 to 120 milliseconds) and is markedly influenced by the autonomic tone.

His potential duration reflects conduction through the short length of the HB that penetrates the fibrous septum. Disturbances of the HB conduction can manifest as fractionation, prolongation (more than 30 milliseconds), or splitting of the His potential (Fig. 9.20).

The HV interval is measured from the onset of the His potential to the onset of the earliest registered surface or intracardiac ventricular activation, and it represents conduction time from the proximal HB through the distal HPS to the ventricular myocardium. The most proximal electrodes displaying the His potential should be chosen, and a large atrial electrogram should accompany the proximal His potential. The HV interval is not significantly affected by the autonomic tone, and it usually remains stable over a wide range of heart rates (indicating differences in autonomic tone). The range of HV intervals in normal subjects is narrow, 35 to 55 milliseconds.

Localization of the Site of Atrioventricular Block

EP testing allows analysis of the HB electrogram, as well as providing atrial and ventricular pacing to uncover conduction abnormalities. A markedly prolonged HV interval (100 milliseconds or longer) is associated with a high incidence of progression to complete heart block. In addition, a His potential 30 milliseconds or longer in duration or that is frankly split into two deflections is indicative of intra-Hisian conduction delay.

When the His potential is recorded during atrial pacing at progressively shorter pacing cycle lengths (PCLs), the AH interval normally gradually lengthens until Wenckebach block develops. The HV interval normally remains constant despite different pacing rates. Abnormal AVN conduction produces Wenckebach block at slower atrial pacing rates than what is normally seen (i.e., at a PCL longer than 500 milliseconds). To determine whether AVN disease is truly present or whether AVN conduction is just under the influence of excessive vagal tone, atropine or isoproterenol may be administered to evaluate for improvement in conduction.

Fig. 9.20 Split His Potential. Split His potentials are observed on His catheter recording obtained in a patient with cardiomyopathy and left bundle branch block. Recording only the distal His signal (H') would give His_{dist} the false impression of normal infranodal conduction ($H'V = 42$ milliseconds). His_{dist} , Distal His bundle; His_{prox} , proximal His bundle; RVA , right ventricular apex.

Infranodal block is present when the atrial electrogram is followed by the His potential but no ventricular depolarization results. Block below the HB is abnormal unless it is associated with short PCLs (350 milliseconds or less) or after sudden increases in atrial rate. Block in the HB can be masked by prolonged AVN conduction time or refractoriness. When block in the AVN develops at a slow pacing rate, atropine may be administered to improve AVN conduction and allow evaluation of the HPS at faster pacing rates.

Selective pacing of the HB can help localize the site of infranodal block (intra- vs. infra-Hisian). HB capture with normal QRS duration is consistent with intra-Hisian site of conduction block, whereby HB pacing recruits fibers in the HB and bundle branches distal to the site of conduction block.⁵³

Site of First-Degree Atrioventricular Block

Atrioventricular node. An AH interval longer than 130 milliseconds with a normal HV interval indicates intranodal conduction delay (see Fig. 9.6). Dual AVN physiology can produce transient, abrupt, or alternating first-degree block caused by block in the fast AVN pathway and conduction down the slow pathway. The change in the PR interval seen on the surface ECG corresponds to a jump in the AH interval viewed on the HB electrogram.

His-Purkinje system. As long as at least one fascicle conducts normally, the HV interval should not exceed 55 milliseconds (or 60 milliseconds in the presence of LBBB). A prolonged HV interval (more than 55 to 60 milliseconds) with or without prolonged His potential duration (more than 30 milliseconds) or a split His potential is diagnostic for HPS disease, even in the presence of a normal PR interval (see Figs. 9.7 and 9.20). A prolonged HV interval is almost always associated with an abnormal QRS because the impairment of intra-Hisian conduction is not homogeneous. Most patients have an HV interval of 60 to 100 milliseconds but only occasionally more than 100 milliseconds. With pure intra-Hisian conduction delay, the AH interval and the distal His-to-ventricular ($H'-V$) interval are normal, whereas the duration of the His potential is longer than 30 milliseconds, with a notched, fragmented, or split His potential. In this case, verification of the origin of the “split H” from the HB (and not part of the atrial or ventricular electrograms) is critical. This can be achieved by dissociation of the His potential from atrial activation with atrial pacing,

adenosine, or vagal stimulation and dissociation of the His potential from ventricular activation by documenting that the HV interval is longer than 30 milliseconds.

Atrium. A prolonged PA interval with normal AH and HV intervals indicates intraatrial conduction delay (see eFig. 9.1).

Site of Type 1 Second-Degree Atrioventricular Block

Atrioventricular node. Wenckebach block in the AVN is characterized by progressive prolongation of the AH interval, until an atrial deflection is not followed by His and ventricular deflections (see Figs. 9.8 and 9.9).

His bundle. A prolonged His potential duration or a split His potential is indicative of intra-Hisian disease. Intra-Hisian Wenckebach block can occur between the two His deflections, characterized by progressive conduction delay until the first His deflection is not followed by the second one.

Bundle branches. In Wenckebach AV block secondary to block below the HB, progressive prolongation of the HV interval is followed by a His deflection without an associated ventricular activation (see Fig. 9.11).

Site of Type 2 Second-Degree Atrioventricular Block

His-Purkinje system. The blocked cycle features atrial and HB deflections without ventricular depolarization (eFig. 9.4 and Fig. 9.21). The conducted beats usually show evidence of infranodal conduction system disease, with a prolonged HV interval, or even a split His potential, and BBB. Multilevel AV block (intranodal and infranodal) can also occur, especially during rapid atrial tachycardias or atrial pacing. Typically, infranodal AV block occurs in the presence of prolonged HPS refractoriness caused by antiarrhythmic agents or during Wenckebach cycles in the AVN (eFig. 9.5).

Site of Third-Degree Atrioventricular Block

Atrioventricular node. Complete heart block at the AVN level is usually seen on the intracardiac tracings as His potentials consistently preceding each ventricular electrogram. The atrial electrograms are dissociated from the HV complexes (Fig. 9.22). Most often, the escape rhythm originates in the HB (with normal QRS preceded by a His potential and normal HV interval); however, in 20% to 50% of patients

eFig. 9.4 Infranodal Block in a Patient With Persistent Atrial Fibrillation (AF) and Recurrent Syncope. (A) Surface electrocardiogram (ECG) recordings show AF with slow ventricular response and left bundle branch block. (B) Intracardiac recordings showing His potentials (*H*), some of which are conducted (HV interval, 124 milliseconds) and some are blocked.

eFig. 9.5 Multiple Levels of Atrioventricular Block. Rapid atrial pacing (at a cycle length of 330 milliseconds) from the high right atrium (*HRA*) shows repeating pattern of atrial impulses with normal AH intervals conducted to the ventricle, atrial impulses associated with AH interval prolongation with block below the His bundle, and atrial impulses associated with atrioventricular nodal block (no His potential). *CS_{dist}*, Distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *His_{dist}*, distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *RVA*, right ventricular apex.

Fig. 9.21 Type 2 Second-Degree Atrioventricular Block. Sinus rhythm is observed with a wide QRS complex. The PR interval of all conducted P waves is constant and slightly prolonged (224 milliseconds). The fourth P wave fails to conduct to the ventricle but is followed by a His potential, suggesting that the level of AV block is infra-Hisian.

Fig. 9.22 Complete Intranodal Atrioventricular (AV) Block. Complete AV block with AV dissociation is observed, and all the P waves fail to conduct despite having ample opportunity for conduction. Note the junctional escape rhythm with a narrow QRS complex and a rate of 45 beats/min, consistent with block in the AVN. Note that the P waves surrounding a QRS complex occur at a faster rate when compared with the P waves that occur sequentially without an intervening QRS complex (ventriculophasic arrhythmia).

Fig. 9.23 Atrial Bigeminy Mimicking 2:1 Atrioventricular (AV) Block. Frequent premature atrial complexes (PACs; A') are observed in a bigeminal pattern. The PACs arrive at the atrioventricular node during the absolute refractory period and fail to conduct to the ventricle, thus mimicking 2:1 AV block. In contrast to 2:1 AV block, the nonconducted P waves are premature (compare with the first A-A interval, which is not interrupted by a PAC) and have different morphology than the conducted sinus P waves.

with chronic AV block, a wide QRS escape rhythm can occur. Rhythms originating in the distal HB can have a QRS preceded by a retrograde His potential or no His potential at all. Those rhythms are usually slower and nonresponsive to atropine. The stability of the HB rhythm can be assessed by noting the effects of overdrive suppression produced by ventricular pacing (in a manner analogous to testing sinus node function); prolonged pauses (i.e., the lack of HB escapes) herald subsequent complete failure of the escape rhythm.

His-Purkinje system. The intracardiac electrogram shows HB deflections consistently following atrial electrograms, but ventricular depolarizations are completely dissociated from the AH complexes. Block below the HB is thus demonstrated.

Exclusion of Other Phenomena

Nonconducted Premature Atrial Complexes

Early PACs can arrive at the AVN during the absolute refractory period and fail to conduct to the ventricle. This condition can be misdiagnosed

as type 1 or type 2 second-degree AV block. Similarly, atrial bigeminy, with failure of conduction of the PACs, can be misinterpreted as 2:1 AV block (Fig. 9.23). In type 2 second-degree AV block, the atrial rhythm is regular, the P-P interval is fairly constant (except for some variation caused by ventriculophasic arrhythmia), the nonconducted P wave occurs on time as expected, and P wave morphology is constant. On the other hand, in the setting of nonconducted PACs, the P wave occurs prematurely and usually has a different morphology from that of the baseline atrial rhythm. Nonconducted PACs can often be hidden in the preceding T wave (Figs. 9.24 and 9.25). In addition, the mere occurrence of PACs (even when conducted) in a trigeminal or quadrigeminal pattern can produce a pattern mimicking Wenckebach periodicity (see eFig. 9.5).

Concealed Junctional Ectopy

Ectopic beats arising from the HB that fail to conduct to both the atria and ventricles can result in retrograde concealment in the AVN, causing

Fig. 9.24 Atrial Ectopy Mimicking Wenckebach Atrioventricular (AV) Block. The surface electrocardiogram shows normal sinus rhythm with four premature atrial complexes (PACs) occurring in a bigeminal pattern. The first three PACs (blue arrows) are conducted and give rise to a pattern that can mimic Wenckebach type I atrioventricular block. The fourth PAC (red arrow) is nonconducted. Note the premature P waves occur early and lie within the preceding T wave (arrows). The last three sinus P waves have no intervening PACs, and the T waves during those beats are clearly different from the ones harboring the PACs. All sinus P waves are conducted with a normal, constant PR interval.

Fig. 9.25 Atrial Trigeminy Mimicking Mobitz Type II Atrioventricular Block. The blocked premature atrial complexes occur in a trigeminal pattern during sinus rhythm, resulting in a pattern that can mimic Mobitz type II atrioventricular block. Note the nonconducted P waves occur early (premature) and lie within the preceding T wave (arrows). All sinus P waves are conducted with a normal, constant PR interval.

either slowing of conduction or block of the following sinus P wave and hence mimicking type 2 second-degree AV block (eFig. 9.6). In this setting, AV block is physiological; however, it can be difficult to differentiate from pathological AV block without EP testing. ECG clues to concealed junctional extrasystoles causing such unexpected events include the following: (1) abrupt, unexplained prolongation of the PR interval; (2) the presence of apparent Mobitz type II block in the presence of a normal QRS; (3) the presence of apparent types 1 and 2 AV

block in the same tracing; and (4) the presence of manifest junctional extrasystoles elsewhere in the tracing (see Fig. 9.12).

Atrioventricular Dissociation

AV dissociation is present when the atria and ventricles depolarize independently of each other. The ventricles are activated by a nonatrial source and are uninfluenced by atrial activity. By definition, there is no retrograde conduction from the ventricles to the atria. AV dissociation

eFig. 9.6 Frequent Premature Atrial Complexes Mimicking Second-Degree Atrioventricular (AV) Block. Sinus rhythm with marked first-degree AV block and bifascicular block (right bundle branch block and left anterior fascicular block). Frequent premature atrial complexes (PACs; *P'*) are observed in a trigeminal pattern. The PACs are conducted to the ventricles; however, they produce a periodicity, thus mimicking Wenckebach AV block. Note that no P waves fail to conduct to the ventricle. Despite the presence of marked His-Purkinje system disease, the marked prolongation of the PR intervals (420 milliseconds) suggests the atrioventricular node as the site of AV conduction delay.

can occur secondary to complete AV block, atrial bradycardia with a faster independent junctional-ventricular escape rhythm, or increased discharge rate of a subsidiary pacemaker that takes control of the ventricular rhythm.

The distinction between AV dissociation and complete AV block is important. In complete AV block the atrial rate is faster than the ventricular rate. For AV block to be diagnosed, the P waves must fail to conduct, given every opportunity for optimal conduction. Thus failure of conduction of all the P waves, even those occurring at long RP intervals and throughout the phases of the ventricular cycle, has to be documented. Occasionally, the rate of the junctional or ventricular rhythm during AV dissociation is only slightly different from that of the atrial rhythm. In this setting the standard ECG may not provide a recording opportunity long enough to verify failure of conduction, because all the P waves recorded on a single ECG recording may not occur at an appropriate time to allow conduction. Thus obtaining ECG recording for an adequate length of time is important (Fig. 9.26). Regularity of both atrial and ventricular rhythms with constantly changing PR relationships, despite the fact that the P wave falls at every conceivable RP interval, and an independent ventricular rate of 40 beats/min or less (faster in congenital complete AV block) are diagnostic of complete AV block. On the other hand, some irregularity of the ventricular rhythm should immediately draw attention to the possibility of intermittent conduction of P waves, which may reflect lesser degrees of AV block or incomplete AV dissociation. Moreover, with complete AV block, the ventricular rate is almost always slower than the atrial rate, whereas in other forms of AV dissociation, the reverse is true. Therefore complete AV block with a junctional or ventricular escape rhythm is one form of AV dissociation. However, AV dissociation (complete or incomplete) can occur in the absence of AV block.

In the setting of atrial bradycardia, the atrial rate can become slower than a subsidiary escape focus from the AV junction or ventricle. When the faster junctional or ventricular escape rhythm is associated with VA block, it results in failure of the atrial impulses to conduct anterogradely secondary to retrograde concealment by the escape rhythm impulses (see Fig. 9.18).

An increase in the discharge rate of a subsidiary pacemaker, such as accelerated junctional rhythm, accelerated idioventricular rhythm, or VT, which then exceeds the normal sinus rate, can result in a competing junctional or ventricular rhythm, in which case the atrial rate is always slower than the ventricular rate (see Fig. 9.26).

AV dissociation can be complete or incomplete. In the setting of complete AV dissociation, both the atrial and ventricular rates remain constant and therefore the PR interval varies, with none of the atrial complexes conducted to the ventricles. In incomplete AV dissociation, ventricular capture beats occur because some of the atrial impulses arrive at the AV junction when the AV junction is no longer refractory. This phenomenon is common in advanced AV block with periodic capture beats.

Echo Beats

AVN echo beats can manifest as “group beating” and be misdiagnosed as Wenckebach block. Verification of constant P-P intervals and P wave morphology during the Wenckebach cycle can avoid such misinterpretation. On the other hand, in the presence of dual AVN physiology, not infrequently Wenckebach AV block can result in AVN echo beats.

Atrial Tachyarrhythmias

Failure of the AVN to conduct during fast atrial tachyarrhythmias (AT or AFL) should not be considered pathological AV block. One of the main physiological roles of the AVN is to safeguard the ventricles from rapid atrial rates. Therefore failure of the AVN to conduct every atrial impulse occurring at a fast rate should be considered a normal physiological finding caused by normal refractoriness. In such situations, terms such as 3:2 and 2:1 AV conduction are more appropriate than 3:2 or 2:1 AV block.

Atrial Fibrillation With Slow Ventricular Rate

AF with slow ventricular response can be misinterpreted as complete AV block. Verification of the regularity of the slow ventricular rhythm is critical. When AV block is present, the escape rhythm is regular, whereas in AF associated with very slow ventricular response, the

Fig. 9.26 Atrioventricular Dissociation. Slow ventricular tachycardia and normal sinus rhythm coexist with slightly different rates and ventricular-atrial dissociation. Sinus P waves are marked by red arrows. Note that no atrioventricular block is present and that, once the sinus P wave had the chance to conduct, it did (blue arrow).

Fig. 9.27 Atrial Fibrillation (AF) With Slow Ventricular Rate. (A) The ventricular rhythm is irregular, indicating that it is the result of conducted atrial beats. (B) The ventricular rhythm is regular, consistent with the presence of complete atrioventricular (AV) block and a regular junctional escape rhythm.

ventricular rhythm is a result of conducted atrial beats and is irregular (Fig. 9.27).

Ventriculophasic Sinus Arrhythmia

Ventriculophasic sinus arrhythmia can be observed whenever there is second- or third-degree AV block, and it is manifest as intermittent differences in the P-P intervals based on their relationship with the QRS complex. The two P waves surrounding a QRS complex have a shortened interval or occur at a faster rate when compared with two P waves that occur sequentially without an intervening QRS complex (see Fig. 9.22). The mechanism of this phenomenon is not certain. However, it has been suggested that ventricular contractions enhance sinus node automaticity by increasing the pulsatile blood flow through the sinus nodal artery and by mechanical stretch on the sinus node.

PRINCIPLES OF MANAGEMENT

Identifying transient or reversible causes for AV conduction disturbances is the first step in management. Withdrawal of any offending drugs, correction of any electrolyte abnormalities, or treatment of any infectious processes (e.g., Lyme disease) or myocardial ischemia should be considered prior to permanent pacing therapy.

Pharmacological therapy (atropine, isoproterenol, epinephrine) can be effective in intranodal AV block but only as a short-term emergency measure until pacing can be accomplished.

Temporary percutaneous or transvenous pacing can be necessary in patients with hemodynamically significant AV block and bradycardia to provide immediate stabilization prior to permanent pacemaker placement or to provide pacemaker support when the block is precipitated by what is presumed to be a transient event, such as ischemia or drug toxicity.²⁵ However, it is important to recognize that transcutaneous pacing does not provide reliable ventricular capture and should be used sparingly. When used, careful hemodynamic and ECG monitoring is mandatory to verify effective ventricular stimulation. Similarly, due to the multitude of complications associated with temporary transvenous pacing (e.g., lead dislodgement, cardiac perforation, patient immobilization), this modality should be used only as a last resort and as briefly as possible. Unless there is a contraindication, positive chronotropic drug infusion is preferred.^{19,20}

Permanent Pacing Therapy

Pacing is the mainstay of treatment for symptomatic AV block (Box 9.1). After all reversible causes are excluded or treated, correlation of symptoms with ECG evidence of AV block is an essential part of the diagnostic strategy. In the setting of intermittent AV block or Wenckebach AV block, ambulatory monitoring often is required to correlate symptoms with the presence and severity of AV conduction abnormalities. As discussed previously, exercise testing can be a useful tool to help confirm the level of block in second- or third-degree AV block associated with a narrow or wide QRS complex. In addition, EP testing can be required in a patient with suspected high-grade AV block as the cause of syncope or presyncope when documentation cannot be obtained noninvasively. Similarly, in patients with coronary artery disease, in whom symptoms can be secondary to AV block or VT, EP testing can be useful in establishing the diagnosis. Some patients with known second- or third-degree block also can benefit from an invasive study to localize the site of AV block to help determine therapy or assess prognosis.²⁵

Third-Degree Atrioventricular Block

Permanent pacemaker implantation is indicated in patients with symptomatic complete AV block, regardless of the site of block. Permanent pacing is also recommended in asymptomatic patients with complete heart block, especially those with documented ventricular pauses longer than 3 seconds or a ventricular escape rhythm of less than 40 beats/min.²⁵

Second-Degree Atrioventricular Block

Permanent pacing is recommended in most patients with symptomatic second-degree AV block, regardless of the site of block. However, in asymptomatic patients, permanent pacemakers may be considered only in patients with infranodal (type 2) second-degree AV block but not those with intranodal type 1 second-degree AV block.²⁵

First-Degree Atrioventricular Block

Permanent pacing is not recommended for asymptomatic first-degree AV delay. However, dual-chamber pacing can be beneficial in some of these patients with marked PR prolongation (more than 300

BOX 9.1 ACCF/AHA/HRS Recommendations for Permanent Pacing in Acquired Atrioventricular Block in Adults

Class I

- Third-degree and advanced second-degree AV block at any anatomic level, associated with any one of the following:
 - Symptomatic bradycardia (including heart failure)
 - Ventricular arrhythmias presumed to result from AV block
 - Arrhythmias and other medical conditions that require drugs that result in symptomatic bradycardia
- Awake, symptom-free patients in sinus rhythm and documented periods of asystole ≥ 3.0 s or any escape rate < 40 beats/min, or with an escape rhythm that is below the AV node
- Average awake ventricular rates of 40 beats/min or faster if cardiomegaly or left ventricular dysfunction is present or if the site of block is below the AV node
- Awake, symptom-free patients with atrial fibrillation and bradycardia with one or more pauses of at least 5 s
- After catheter ablation of the AV junction
- Postoperative AV block that is not expected to resolve
- Neuromuscular diseases, such as myotonic muscular dystrophy, Kearns-Sayre syndrome, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy, with or without symptoms
- Second-degree AV block with associated symptomatic bradycardia regardless of type or site of block
- Second- or third-degree AV block during exercise in the absence of myocardial ischemia
- Persistent third-degree AV block at any anatomic site in asymptomatic patients with average awake ventricular rates of 40 beats/min or faster if cardiomegaly or LV dysfunction is present or if the site of block is below the AV node

Class IIa

- Persistent third-degree AV block with an escape rate > 40 beats/min in asymptomatic adult patients without cardiomegaly
- Asymptomatic second-degree AV block at intra-Hisian or infra-Hisian levels found at electrophysiological study
- First- or second-degree AV block with symptoms similar to those of pacemaker syndrome or hemodynamic compromise
- Asymptomatic type II second-degree AV block with a narrow QRS; when type II second-degree AV block occurs with a wide QRS, including isolated right bundle branch block, pacing becomes a class I recommendation

Class IIb

- Neuromuscular diseases such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with any degree of AV block (including first-degree AV delay), with or without symptoms, because there may be unpredictable progression of AV conduction disease
 - AV block in the setting of drug use and/or drug toxicity when the block is expected to recur even after the drug is withdrawn

Class III

- Asymptomatic first-degree AV delay
- Asymptomatic type I second-degree AV block at the AV node level or that which is not known to be intra-Hisian or infra-Hisian
 - AV block that is expected to resolve and is unlikely to recur (e.g., drug toxicity, Lyme disease, or transient increases in vagal tone, or during hypoxia in sleep apnea syndrome in the absence of symptoms)

ACCF, American College of Cardiology Foundation; AHA, American Heart Association; AV, atrioventricular; HRS, Heart Rhythm Society. Modified from Epstein AE, DiMarco JP, Ellenbogen KA, et al. 2012 ACCF/AHA/HRS focused update incorporated into the ACCF/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2013;61:e6–75.

milliseconds) and symptoms similar to those of pacemaker syndrome (see later), as well as in patients with LV dysfunction and heart failure symptoms in whom a shorter AV interval is expected to lead to hemodynamic improvement, presumably by improving ventricular filling and reducing diastolic mitral regurgitation. Nonetheless, the benefit of pacing with optimized AV synchrony (with a shorter AV delay) should be weighed against the potentially detrimental effects of RV pacing and resultant ventricular dyssynchrony.^{25,19}

Atrioventricular Block Post Acute Myocardial Infarction

Temporary pacing is sometimes required in patients with acute MI (more often in anterior than inferior wall MI). Patients with asymptomatic first-degree or type 1 second-degree AV block do not require pacing. However, patients with type 2 second-degree or complete AV block, temporary pacing should be considered, even if they are asymptomatic. Isoproterenol should be used with extreme caution or not at all in patients with acute MI. Importantly, acute temporary transvenous pacing in these patients is associated with a 6% risk of cardiac tamponade. This should be carefully considered when determining optimal treatment strategy.^{19,20}

In patients with acute MI and high-grade AV block, the conduction abnormality is present upon hospital admission in more than 50% of patients and within 48 hours in the majority of patients. In patients treated by primary percutaneous coronary intervention, AV block is predominantly transient, most often resolves spontaneously within a

few days. Pacemaker implantation is required in only 9% patients. Importantly, these patients continue to have high mortality, despite pacing.^{19,20}

In the setting of acute MI, the criteria for permanent pacing depends less on the presence of symptoms (Box 9.2). If type 2 second-degree or complete AV block persists once past the periinfarct period, permanent pacing is indicated. Even if the type 2 or third-degree AV block was transient but associated with BBB that persists following resolution of the AV block, permanent pacing may improve long-term survival.²⁵

Iatrogenic Atrioventricular Block

Permanent pacing is recommended for persistent type 2 second- or third-degree AV block complicating cardiac interventional or surgical procedures (e.g., aortic valve replacement), even in the absence of symptoms. Importantly, early conduction abnormalities occurring after such procedures are often transient, caused by local inflammation near the AV conduction system. Hence, when the patient is hemodynamically stable or already has a functional temporary pacemaker, some delay before committing to a permanent pacemaker may be appropriate.³⁹ However, the duration of “watchful waiting” is not defined and can vary in different settings; therefore the decision for permanent pacing is at the physician’s discretion. In addition, patients with transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block can occasionally develop high-degree AV block later

BOX 9.2 ACCF/AHA/HRS Recommendations for Permanent Pacing in Atrioventricular Block With Acute Myocardial Infarction

Class I

- Persistent second-degree AV block in the HPS with bilateral bundle branch block or third-degree AV block within or below the HPS after ST-segment elevation MI
- Transient advanced (second- or third-degree) infranodal AV block and associated bundle branch block; if the site of block is uncertain, an electrophysiology study may be necessary
- Persistent and symptomatic second- or third-degree AV block

Class IIb

- Persistent second- or third-degree AV block at the AV node level, even in the absence of symptoms

Class III

- Transient AV block in the absence of intraventricular conduction defects
- Transient AV block in the presence of isolated left anterior fascicular block
- New bundle branch block or fascicular block in the absence of AV block
- Persistent asymptomatic first-degree AV delay in the presence of bundle branch block or fascicular block

ACCF, American College of Cardiology Foundation; AHA, American Heart Association; AV, atrioventricular; HPS, His-Purkinje system; HRS, Heart Rhythm Society; MI, myocardial infarction.

Modified from Epstein AE, DiMarco JP, Ellenbogen KA, et al. 2012 ACCF/AHA/HRS focused update incorporated into the ACCF/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2013;61:e6–75.

in the postoperative course. Accordingly, extended cardiac monitoring might be reasonable in patients deemed to be at high risk. If unexplained syncope occurs in these patients, paroxysmal AV block should be suspected.^{25,19}

Congenital Atrioventricular Block

In children (beyond the first year of life) with congenital AV block, pacemaker implantation is recommended for those with symptomatic bradycardia or chronotropic incompetence. Permanent pacing is also recommended in asymptomatic patients who have a wide QRS escape rhythm, complex ventricular ectopy, ventricular dysfunction, inappropriately slow average ventricular rate (fewer than 50 beats/min), or abrupt pauses in ventricular rate that are two or three times the basic cycle length. The value of permanent pacing is questionable in asymptomatic patient with congenital third-degree AV block with an acceptable rate, a narrow QRS complex, and normal ventricular function (Box 9.3).²⁵

Vagally Mediated Atrioventricular Block

Vagally mediated AV block is localized within the AVN and generally is benign. When the AV block is associated with neurocardiogenic syncope, avoidance of triggering and predisposing factors and noninvasive therapy are effective and are preferred to pacing therapy. Nonetheless, permanent pacing may be considered highly selected patients, such as those significantly older than 40 years and patients who experience frequent recurrences associated with repeated injury, limited prodromes, and documented asystole (Fig. 9.28). Even in this subgroup of

BOX 9.3 ACCF/AHA/HRS Recommendations for Permanent Pacing for Atrioventricular Block in Children, Adolescents, and Patients With Congenital Heart Disease

Class I

- Advanced second- or third-degree AV block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output
- Congenital third-degree AV block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction
- Congenital third-degree AV block in the infant with a ventricular rate less than 55 beats/min or with congenital heart disease and a ventricular rate less than 70 beats/min
- Postoperative advanced second- or third-degree AV block that is not expected to resolve or that persists at least 7 days after cardiac surgery

Class IIa

- Congenital third-degree AV block beyond the first year of life with an average heart rate less than 50 beats/min, abrupt pauses in ventricular rate that are two or three times the basic cycle length, or associated with symptoms due to chronotropic incompetence
- Congenital heart disease and impaired hemodynamics due to sinus bradycardia or loss of AV synchrony
- Unexplained syncope in the patient with prior congenital heart surgery complicated by transient complete heart block with residual fascicular block after a careful evaluation to exclude other causes of syncope

Class IIb

- Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block
- Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and normal ventricular function

Class III

- Transient postoperative AV block with return of normal AV conduction in the otherwise asymptomatic patient
- Asymptomatic bifascicular block with or without first-degree AV delay after surgery for congenital heart disease in the absence of prior transient complete AV block
- Asymptomatic type I second-degree AV block
- Asymptomatic sinus bradycardia with the longest relative risk interval less than 3 s and a minimum heart rate more than 40 beats/min

ACCF, American College of Cardiology Foundation; AF, atrial fibrillation; AHA, American Heart Association; AV, atrioventricular; HRS, Heart Rhythm Society.

Modified from Epstein AE, DiMarco JP, Ellenbogen KA, et al. 2012 ACCF/AHA/HRS focused update incorporated into the ACCF/AHA/HRS 2008 guidelines for device-based therapy of cardiac rhythm abnormalities: a report of the American College of Cardiology Foundation/American Heart Association Task Force on Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol*. 2013;61:e6–75.

patients, syncope continues to recur in up to 25% post pacemaker implantation, likely due to the coexistence of a vasodepressor reflex.⁴⁰

Permanent pacing is recommended for patients with syncope due to carotid sinus hypersensitivity or those with syncope without clear provocative events when carotid sinus massage precipitates a cardioinhibitory response of 3 seconds or longer. Pacemaker implantation is not indicated asymptomatic hypersensitive carotid sinus massage response.^{25,40,42}

Fig. 9.28 Asystole Associated With Neurocardiogenic Syncope. Implantable loop recorder documentation of syncope due to vasovagal cardioinhibitory response. (A) Heart rate trend during 4-minute loop recording. Initially, the heart rate is stable at 90 beats/min and gradually falls at the time of syncope. (B) Expanded electrocardiogram. The four strips are continuous and show progressive slowing of the heart rate culminating in a long asystolic pause (greater than 10 seconds), followed by recovery of a slow rhythm.

Pacemaker Device and Mode Selection for Atrioventricular Block

In patients with persistent or intermittent AV block and those at risk of developing AV block requiring ventricular pacing, single-chamber ventricular (VVI), dual-chamber (DDD), or single-lead AV (VDD) pacemaker implantation may be considered (Box 9.4). In general, DDD pacing is the preferred pacing system in the majority of patients with AV block. In addition, regardless of the pacing system used, cardiac resynchronization therapy should be considered in patients with AV block and LV systolic dysfunction who are expected to require high percentage (more than 40%) of ventricular pacing.⁵⁴

DDD and VDD Pacing

Compared with VVI pacing, VDD and DDD pacemakers offer several advantages: First, both systems have the capability to maintain AV synchrony, which can be of significant hemodynamic benefit in patients with LV systolic or diastolic dysfunction, who depend on optimized preload, improved exercise time, functional status, and quality of life, especially in younger, active patients with few comorbidities. Second, in patients with AV block but normal sinus node function, both DDD and VDD pacemakers can preserve AV synchrony and physiological chronotropic response driven by the sinus node rather than by imperfect rate-adaptive algorithms. Third, in patients with only intermittent AV block, VDD and DDD pacemakers can help to promote intrinsic ventricular activation and minimize unnecessary RV pacing that can be

hemodynamically detrimental in many patients. Fourth, device diagnostics available in VDD and DDD pacemakers permit detection of episodes of atrial tachyarrhythmias, which may result in therapeutic interventions, including therapy for stroke prevention.⁵⁴

The VDD pacing systems use a single lead with a series of electrodes for atrial sensing and ventricular pacing and sensing and hence enables atrial-tracking ventricular pacing and restores AV synchrony without the need for an additional atrial lead. As compared with DDD pacemakers, VDD pacemakers offer the advantage of simpler implantation and less risk of procedure complications (in particular, less risk of lead dislodgement) and can be of particular advantage in the younger patient, such as the patient with congenital heart block who might expect multiple system revisions over his lifetime. Nonetheless, VDD pacemakers are used very infrequently (less than 1% of implanted pacemakers in the United States), mostly due to the concern of the potential need for atrial pacing if sinus node dysfunction (SND) develops and the relatively poor long-term performance of the atrial sensing ability of the lead.⁵⁴

VVI Pacing

VVI pacing has limited role in patients with AV block and normal sinus rhythm, given the lack of AV synchrony and the associated pacemaker syndrome (see later). However, VVI or VVIR pacing is adequate for patients with permanent AF and bradycardia and may also be considered post AV junction ablation in patients with intermittent AF who are expected to have high rate of progression to persistent or permanent AF and rhythm control strategies are no longer pursued. In patients

BOX 9.4 HRS/ACCF Recommendations for Pacemaker Device and Mode Selection for Atrioventricular Block

Class I

- Dual-chamber pacing is recommended in patients with AV block
- Single-chamber ventricular pacing is recommended as an acceptable alternative to dual-chamber pacing in patients with AV block who have specific clinical situations that limit the benefits of dual-chamber pacing. These include, but are not limited to, sedentary patients, those with significant medical comorbidities likely to impact clinical outcomes, and those in whom technical issues, such as vascular access limitations, preclude or increase the risk of placing an atrial lead
- Dual-chamber pacing is recommended over single-chamber ventricular pacing in adult patients with AV block who have documented pacemaker syndrome

Class IIa

- Single-lead, dual-chamber VDD pacing can be useful in patients with normal sinus node function and AV block (e.g., the younger patient with congenital AV block)
- VVI pacing can be useful in patients following AV junction ablation, or in whom AV junction ablation is planned, for rate control of AF due to the high rate of progression to permanent AF

Class III

- Dual-chamber pacing should not be used in patients with AV block in permanent or longstanding persistent AF in whom efforts to restore or maintain sinus rhythm are not planned

ACCF, American College of Cardiology Foundation; AF, atrial fibrillation; AV, atrioventricular; HRS, Heart Rhythm Society. Modified from Gillis AM, Russo AM, Ellenbogen KA, et al. HRS/ACCF expert consensus statement on pacemaker device and mode selection. *J Am Coll Cardiol*. 2012;60:682–703.

with permanent AF and AV block, rate-responsive pacing (VVIR) is generally preferred to fixed-rate VVI pacing because of the associated improvement of symptoms, exercise tolerance, and quality of life. Of note, setting the minimum pacing rate to 70 beats/min has been suggested to help to compensate for loss of active atrial filling.

In addition, back-up VVI pacing may be considered in patients with only “paroxysmal” AV block who are not expected to require frequent pacing, and can also be an appropriate choice for inactive or incapacitated patients and those with significant morbidities and poor clinical prognosis. Although atrial-based pacing was shown to significantly reduce the risk of AF and stroke compared with VVI in patients with SND, the benefit may not be of a similar magnitude in patients with AV block as the indication for pacing therapy because the incidence of AF in the latter population is lower compared with those with a SND indication for pacing. In addition, DDD pacing was not shown to reduce the risk of heart failure or the risk of death from all causes or from cardiovascular causes as compared with VVI pacing in the AV block patient population.⁵⁴

Pacemaker Syndrome

Suboptimal AV synchrony or AV dyssynchrony is associated with several detrimental hemodynamic consequences that lead to a constellation of symptoms (including fatigue, weakness, effort intolerance, chest discomfort, dyspnea, confusion, dizziness, presyncope, or syncope) known as the “pacemaker syndrome.”⁵⁴

AV dyssynchrony can cause significant reduction in cardiac output, especially in patients with reduced ventricular compliance and diastolic dysfunction (due to aging or hypertensive, hypertrophic, or restrictive cardiomyopathy), who are particularly sensitive to loss of atrial contribution to ventricular filling. Reduction of cardiac output causes reflex sympathetic activation. Furthermore, atrial contraction against closed mitral and tricuspid valves (which is further promoted in patients with intact retrograde ventriculoatrial conduction) can cause uncomfortable pulsation in the neck (cannon a waves) and abdomen, headache, cough, and jaw pain. The resultant increase in LA pressure and LV filling pressure cause increased plasma levels of atrial natriuretic peptide and B-type natriuretic peptide, potent peripheral venous, and arterial vasodilators.

Although pacemaker syndrome can occur with any pacing mode, it occurs most commonly with VVI pacing in patients who are in sinus rhythm (reported in up to 83%). However, pacemaker syndrome severe enough to warrant reprogramming from VVI to DDD pacing has been reported in only 25% to 30% of patients.⁵⁴

Ventricular Pacing Site

Right Ventricular Apical Pacing

The RV apex has been the traditional site of choice for permanent ventricular pacing, mainly due to technical aspects such as a stable lead position given the available electrode design. However, chronic apical RV pacing has been associated with deleterious hemodynamic effect on LV systolic function. Electrical and mechanical dyssynchrony induced by RV pacing can cause LV systolic dysfunction (“pacing-induced cardiomyopathy”) and heart failure. In fact, new-onset heart failure can be observed in approximately 9% of patients receiving RV pacing for acquired second- or third- degree AV block at 1-year follow-up and 20% after a median follow-up of nearly 10 years. It is important to note that pacing-induced cardiomyopathy can develop as early as 1 month and as late as 9 years after pacemaker implantation.⁵⁵

Male gender, prior heart failure hospitalization, low baseline LVEF, coronary artery disease, wider native QRS duration, wider paced QRS duration after implantation, and higher burden of RV pacing appear to predict a higher risk for developing pacing-induced cardiomyopathy. Although an RV pacing burden of 40% or more has been traditionally considered the cutoff at which risk for pacing-induced cardiomyopathy begins, accumulative pacing burdens as low as 20% have been found to precipitate cardiomyopathy, albeit with a lower incidence.⁵⁵

Nonapical Right Ventricular Pacing

Concern about RV apical pacing has driven an examination of nonapical RV sites, including the RVOT and RV mid or low septum. Although these sites can potentially provide more physiological LV activation and less cardiac dyssynchrony, presumably due to its closer proximity to the HPS, there is as yet no conclusive evidence that supports the superiority of these pacing sites (in terms of quality of life, functional tests, or morbidity and mortality) compared with RV apical pacing.^{56,57,58}

Most studies addressing this issue were limited by small sample sizes, limited follow-up intervals, different patient characteristics, and lack of standardization and verification of pacing site selection, which do not allow the advantages of septal pacing to be categorically determined. Nonetheless, no study has demonstrated inferiority of non-RV apical pacing, and many data point to the contrary. The subgroups benefiting the most from nonapical RV pacing were patients with LV systolic dysfunction.^{56,57,58,59}

Biventricular Pacing

Biventricular pacing can potentially prevent LV remodeling and heart failure caused by conventional RV pacing in patients abnormal LV systolic function and is currently recommended for in patients with LV

dysfunction (LVEF $\leq 50\%$) and advanced AV block and expected frequent (greater than 40%) ventricular pacing.⁶⁰

Although studies have suggested some value for prophylactic biven- tricular pacing in patients with AV block and normal LVEF, the benefit seems marginal and the evidence is not yet sufficiently strong to support widespread adoption of such strategy. No validated risk stratification system currently exists to identify who of these patients would benefit most from biven- tricular pacing. Currently, the best strategy seems to be to evaluate LVEF before pacemaker implantation.^{61,55}

His Bundle Pacing

Direct HB pacing (with the pacing electrode positioned in the mem- branous septum) or para-Hisian pacing can enable physiological pacing in patients without distal conduction disease by recruiting the native HPS, thus avoiding electrical dyssynchrony and potentially preventing pacing-induced cardiomyopathy and heart failure (Figs. 9.29 and 9.30).^{53,62}

However, HB pacing has not gained widespread acceptance in clinical practice because of perceived procedural complexity. Selective HB pacing

can be technically difficult to accomplish reliably and typically requires longer procedure and fluoroscopy times than traditional RV pacing. In addition, HB pacing can be associated with comparatively higher lead dislodgement rates and increasing pacing capture thresholds over time, which can lead to faster battery drain. Nonetheless, recent studies at experienced centers demonstrated safety and feasibility of such an approach in more than 80% of unselected patients referred for pace- maker implantation.^{62–65}

HB pacing is not applicable to patients with native block in the HPS. However, it is important to recognize that HB pacing can normal- ize intraventricular conduction in a large proportion of patients with infranodal AV block who previously had chronic BBB. Longitudinal dissociation of the HB with disease affecting the fibers destined to be right or left bundle branch (rather than disease in the bundle branch itself) may explain this observation. In this setting, HB pacing can recruit HB and bundle branches distal to the site of block and correct the conduction abnormalities. Other mechanisms also have been pro- posed to explain this observation.^{53,66}

Fig. 9.29 Direct His Bundle Pacing. *Top*, The 12-lead electrocardiogram of a patient with complete heart block with narrow QRS escape rhythm. *Middle*, Intracardiac electrogram recorded from the permanent His bundle pacing lead at the time of implantation. Note the His bundle electrogram (H) with injury current (arrow) followed by ventricular electrogram (V). *Bottom*, His bundle pacing. The pacing spike (circle) is followed by an isoelectric interval of 40 milliseconds and QRS complexes identical to the intrinsic rhythm. (From Vijayaraman P, Naperkowski A, Ellenbogen KA, Dandamudi G. Electrophysiologic insights into site of atrioventricular block lessons from permanent His bundle pacing. *JACC Clin Electrophysiol*. 2015;1:571–581, with permission.)

Fig. 9.30 Location of Direct His Bundle (HB) Pacing Lead. Images from chest x-ray (A–B), transthoracic echocardiography (C), and cardiac computed tomography (D–F) showing the location of the direct HB pacing lead. Note that the electrode position is above the plane of the tricuspid valve (TV), in the supraventricular portion of the membranous septum below the level of right coronary cusp of the aortic valve. AV, Atrioventricular; CT, computed tomography; IVS, interventricular septum; Lat, lateral; MV, mitral valve; PA, postero-anterior; RCC, right coronary cusp. Normally, the entire mass of ventricular myocardium is depolarized in about 80 to 100 milliseconds. This requires highly synchronous electrical activation of the ventricular myocardium, which can be achieved only through the rapidly conducting His-Purkinje system (HPS). The term *intraventricular conduction disturbances* (IVCDs) refers to abnormalities in the intraventricular propagation of supraventricular impulses resulting in changes in the morphology and/or duration of the QRS complex. These changes in intraventricular conduction can be fixed and present at all heart rates, or they can be intermittent (transient). They can be caused by structural abnormalities in the HPS or ventricular myocardium, functional refractoriness in a portion of the conduction system (i.e., aberrant ventricular conduction), or ventricular preexcitation over a bypass tract.¹

TRANSIENT BUNDLE BRANCH BLOCK

The term *aberration* is used to describe transient bundle branch block (BBB) and usually does not include persistent QRS abnormalities caused by persistent BBB, preexcitation, or the effect of drugs. Transient BBB can have several mechanisms, including acceleration-dependent block, pause-dependent block, and concealed conduction. These mechanisms of aberration can occur anywhere in the HPS and, unlike in chronic BBB, the site of block during aberration can shift. Right bundle branch block (RBBB) is the most common pattern of aberration, perhaps in part due to the thin nature of its anatomy, occurring in 80% of patients with aberration and in up to 100% of cases of aberration in normal hearts.

Acceleration-Dependent Bundle Branch Block

Conduction velocity depends, in part, on the rate of rise of phase 0 (dV/dt) of the action potential and the height to which it rises. These factors, in turn, depend on the membrane potential at the time of stimulation. The more negative the membrane potential, the more sodium (Na^+) channels are available for activation, allowing for a greater influx of Na^+ into the cell during phase 0 and, hence, larger action potential amplitude, fast depolarizing Na^+ current, and faster conduction velocity.²

On the other hand, when stimulation occurs during phase 3 of the action potential, before full voltage recovery and at less negative

transmembrane potentials, a portion of Na^+ channels is still refractory and unavailable for activation. Consequently, the Na^+ current and phase 0 of the action potential are reduced, and the resulting action potential has slower conduction properties and is more susceptible to conduction block (Fig. 10.1).

“Phase 3 block” (also called “voltage-dependent block”) occurs when an impulse arrives at tissues that are still refractory due to incomplete repolarization. Functional or physiological phase 3 aberration can occur in normal fibers if the impulse is sufficiently premature to encroach on the physiological refractory period of the preceding beat. This is commonly seen with a premature atrial complex (PAC) with a very short coupling interval that attempts to depolarize the HPS during phase 3 of the action potential and, hence, is conducted aberrantly, most often with RBBB.²

Manifestations of phase 3 block include BBB and fascicular block, as well as complete atrioventricular (AV) block. Transient left bundle branch block (LBBB) is less common than RBBB (only 25% of phase 3 aberration is of the LBBB type). The block usually occurs in the very proximal portion of the right bundle (RB). Phase 3 block constitutes the physiological explanation of several phenomena, including aberration caused by premature excitation, Ashman phenomenon, and acceleration-dependent aberration.

Importantly, in the presence of HPS disease, the mechanism of acceleration-dependent aberration may no longer be related to phase 3 block. In this setting, aberration can be precipitated by premature or shorter-coupled impulses occurring well after completion of phase 3 of the action potential. This type of block or aberrancy is usually a sign of conduction system disease. In normal myocardial cells, recovery of electrical excitability coincides in time with voltage recovery, that is, the end of the action potential. The resting membrane potential remains polarized throughout diastole. In contrast, under pathological conditions (e.g., ischemia, hyperkalemia, hypoxemia, acidosis), cardiomyocytes can have a less negative resting membrane potential. Hence, a portion of Na^+ channels remains closed and unavailable for activation throughout diastole. This results in reduced upstroke velocity and smaller amplitude of the action potential. At more depolarized resting potentials, the Na^+ current cannot be activated, though a strong stimulus can still induce a “slow response” action potential carried out by the slowly depolarizing calcium current. The “slow response” is characterized by slow conduction

Fig. 10.1 Mechanisms of Transient Bundle Branch Block. Diagrammatic illustration of the responses of a normal ventricular myocyte action potential (AP, *top*) and a depressed AP (*bottom*) to premature stimulation. *Top*, So-called phase 3 or voltage-dependent refractoriness. The first stimulus (arrow) falls on an early phase 3 and fails to elicit a response. The second stimulus falls in late phase 3 and results in an abbreviated, slowly rising AP of low amplitude. The third stimulus that falls at the end of repolarization results in a full AP. The bottom recording illustrates postrepolarization refractoriness (arrows) in a depressed fiber. Because of delayed recovery of excitability, despite full repolarization after the second action potential, a depolarizing stimulus applied very early in diastole is incapable of bringing the cell to the threshold potential (broken horizontal line). Thus the stimulus fails, and only a subthreshold depolarization is seen. When a similar stimulus is applied later in diastole, the cell is activated after a substantial delay. (From El-Sherif N, Jalife J. Paroxysmal atrioventricular block: are phase 3 and phase 4 block mechanisms or misnomers? *Heart Rhythm*. 2009;6:1514–1521.)

properties and refractoriness that can extend beyond the end of the action potential, a phenomenon known as “post-repolarization refractoriness.” As a result, a premature stimulus occurring during the early phase of diastole may fail to trigger a propagating action potential and, hence, manifest as block or aberration. Furthermore, the diseased HPS cells with depressed resting membrane potential are vulnerable to the phenomenon of concealed conduction and rate-dependent repetitive conduction block (see below), which can also mediate, at least in part, acceleration-dependent block.^{2,3}

Aberration Caused By Premature Excitation

Premature excitation can cause aberration by encroaching on the refractory period of the bundle branch prior to full recovery of the action potential, namely during so-called voltage-dependent refractoriness (see Fig. 4.28). In normal hearts, this type of aberration is almost always in the form of RBBB (Fig. 10.2), whereas such aberration in the abnormal heart can be that of RBBB or LBBB.

At normal heart rates, the effective refractory period (ERP) of the RB exceeds that of the atrioventricular node (AVN), His bundle (HB), and left bundle (LB). At faster heart rates, the ERP of both bundle branches shortens. However, RB ERP shortens to a greater degree than LB ERP, so that the duration of the refractory periods of the two bundles crosses over, and LB ERP becomes longer than that of the RB. This explains the tendency of aberration to be in the form of RBBB when premature excitation occurs during normal heart rates and in the form of LBBB when it occurs during fast heart rates.

Ashman Phenomenon

The Ashman phenomenon refers to aberration occurring when a short cycle follows a long one (long-short cycle sequence) (Fig. 10.3). Aberrancy is caused by the physiological changes of the conduction system

Fig. 10.2 Aberrantly Conducted Premature Atrial Complexes. Sinus rhythm with atrial couplets. Note that the premature atrial complexes are conducted with right bundle branch block aberrancy (phase 3 block).

Fig. 10.3 Ashman Phenomenon. A premature atrial complex (PAC, red arrow) during sinus rhythm induces atrial fibrillation (AF). Note that the PAC is conducted with right bundle branch block (RBBB) aberrancy (phase 3 block). During AF, long-short cycle sequences occur repeatedly and are associated with RBBB aberrancy (Ashman phenomenon, phase 3 block). Note that the aberrantly conducted complex (blue arrows) during AF occurs at variable coupling intervals to the preceding beats.

refractory periods associated with the R-R interval. Normally, the refractory period of the HPS lengthens as the heart rate slows and shortens as the heart rate increases, even when heart rate changes are abrupt. Thus, aberrant conduction can result when a short cycle follows a long R-R interval. In this scenario, the QRS complex that ends the long pause (i.e., long R-R interval) is conducted normally but creates a prolonged ERP of the bundle branches. If the next supraventricular impulse approaches the bundle branches after a short coupling interval, it may be conducted aberrantly because one of the bundles is still refractory as a result of a lengthening of the refractory period following the immediately preceding QRS (phase 3 block) (eFig. 10.1). RBBB aberration is more common than LBBB in this setting because at heart rates usually present, the RB has a longer ERP than the LB.

The Ashman phenomenon can occur during second-degree AV block (see eFig. 9.3), but it is most common during atrial fibrillation (AF), in which it was originally described, whereby the irregularity of the ventricular response results in frequently occurring long-short cycle sequences. Of note, aberration caused by the Ashman phenomenon can persist for several cycles. The persistence of aberration can reflect a time-dependent adjustment of refractoriness of the bundle branch to the abrupt change in cycle length (CL), or it can be the result of concealed transseptal activation (see later).

The aberrancy can be present for one beat and have a morphology resembling a premature ventricular complex (PVC), or it can involve several sequential complexes, mimicking ventricular tachycardia (VT). In the setting of aberrancy during AF, the mere “long-short cycle sequence” characteristic of the Ashman phenomenon may not be helpful in differentiating aberration from ventricular ectopy. Although a long cycle (pause) sets the stage for the Ashman phenomenon, it also tends to precipitate ventricular ectopy. Furthermore, concealed conduction

TABLE 10.1 Distinguishing Aberrantly Conducted Complexes from Premature Ventricular Complexes During Atrial Fibrillation		
	Aberration	Premature Ventricular Complexes
Onset sequence	Long-short	Short-long
Rate parity between periods of wide versus narrow QRS complexes	Similar rates	Different rates
Coupling intervals from prior narrow QRS complexes	Variable over several occurrences	Same or similar over several occurrences
Regularity of consecutive wide QRS complexes	Irregular	Relatively regular
Fusion complexes	Absent	May be present

occurs frequently during AF and therefore it is never possible to know from the surface electrocardiogram (ECG) exactly when a bundle branch is activated. Thus, if an aberrant beat does end a long-short cycle sequence during AF, it can be because of refractoriness of a bundle branch secondary to concealed conduction into it, rather than because of changes in the length of the ventricular cycle.

Nevertheless, there are several features of ventricular ectopy that can help distinguish a PVC from an aberrantly conducted “Ashman beat” during AF (Table 10.1). PVCs are usually followed by a longer R-R cycle, indicating the occurrence of a compensatory pause, the result

Fig. 10.1 Atrial Tachycardia With Variable Atrioventricular Conduction and Intermittent Aberrancy. Left, atrial tachycardia (AT) with 2:1 atrioventricular (AV) conduction and normal QRS morphology is observed. Once 1:1 AV conduction occurs (QRS 3), left bundle branch block (LBBB) aberration develops (caused by long-short cycle sequence, phase 3 block). LBBB aberration is also observed during QRS 4, likely secondary to concealed transseptal conduction causing perpetuation of aberration. After a pause, both bundle branches recover from refractoriness producing a normal QRS 5. Ashman phenomenon (long-short cycle sequence) explains phase 3 block during QRS 6, but this time it manifests as a right bundle branch block (RBBB) pattern. This is because activation during QRS 4 propagated down the right bundle branch (RB) and across the septum, thus activating the left bundle branch (LB) retrogradely after some delay (concealed transseptal conduction), so that the LB-LB interval (between QRS 4 and QRS 5) resulted in a shorter effective refractory period (ERP) of the LB following QRS 5. Conversely, the RB-RB interval (between QRS 4 and QRS 5) was longer and, consequently, the ERP of the RB was still prolonged following QRS 5, thereby setting the stage for a long-short cycle sequence of the RB but not the LB. Therefore, RBBB (rather than LBBB) aberration develops. RBBB aberration during QRS complexes 7 and 8 is secondary to either concealed transseptal conduction or rate-dependent aberration. However, because LBBB (rather than RBBB) was observed during QRS 4 (although QRS 4 occurred following a similar cycle length to that of QRS 8), concealed transseptal conduction is more likely to be the mechanism of aberration. After a pause, both bundle branches recover from refractoriness to produce a normal QRS 9. Long-short cycle sequence explains phase 3 block during QRS 10, but this time it manifests as LBBB. This is because activation during QRS 8 propagated down the LB and across the septum, thus activating the RB after some delay (concealed transseptal conduction). The result is that the RB-RB interval (following QRS 8) and ERP of the RB became shorter, whereas the LB-LB interval (following QRS 8) was longer. Consequently, the ERP of the LB was still prolonged following QRS 9, thereby setting the stage for a long-short cycle sequence and LBBB aberration. LBBB aberration during QRS 11 is caused by concealed transseptal conduction. The Ashman phenomenon (long-short cycle sequence) underlies RBBB aberration during QRS 14. *HRA*, High right atrium.

Fig. 10.4 Tachycardia-dependent (Phase 3) Block. The tracing shows sustained supraventricular tachycardia. Initially, the QRS is of normal morphology. Tachycardia-dependent (phase 3) right bundle branch block develops in the middle of the tracing and is sustained for a few beats. Delivery of a late ventricular extrastimulus (arrow) during the tachycardia preexcites the right bundle branch (and either peels back or shortens its refractoriness) and restores normal conduction.

of retrograde conduction into the AVN and anterograde block of the impulse originating in the atrium. Hence, the presence of consistently long R-R cycles after the aberrated beats is suggestive of PVCs. A ventricular origin is also likely when there is a fixed coupling cycle between the normal and aberrant QRS complexes. Additionally, the absence of aberrancy despite the presence of comparable long-short cycle sequences elsewhere in the rhythm recording argues against aberrancy and is more consistent with ventricular ectopy. Finally, QRS morphology inconsistent with LBBB or RBBB aberrancy argues against aberration and is consistent with ventricular origin of the QRS complex (eFig. 10.2).

Aberration Caused by Heart Rate Acceleration

As the heart rate accelerates, the HPS refractory period shortens allowing for normal 1:1 conduction at the faster atrial rate. However, refractoriness of the HPS eventually reaches a critical value beyond which it can no longer shorten in response to a further increase in the atrial rate; at this point, BBB or AV block can occur. Acceleration-dependent BBB is a result of failure of the action potential of the bundle branches to shorten in response to acceleration of the heart rate (Fig. 10.4). As noted previously, the ERP of the RB normally shortens at faster heart rates to a greater degree than that of the LB; this finding explains the more frequent RBBB aberration at longer CLs (i.e., at slower heart rates) and LBBB aberration at shorter CLs.

Notably, during slowing of the heart rate, intraventricular conduction often fails to normalize at the critical CL, and aberration persists at cycles longer than the critical cycle that initiated the aberration. Once acceleration-dependent BBB is established, the actual cycle for the blocked bundle does not begin until approximately halfway through the QRS complex because of concealed transseptal conduction (see later); thus, it is necessary for the heart rate to slow down more than would be expected to reestablish normal conduction.

Occasionally, with increasing heart rate or persistence of fast heart rate, acceleration-dependent aberration can disappear. The normalization of a previously aberrant QRS complex can be explained by shortening of the ERP of the bundle branches to a greater degree than that of the AVN, by a time-dependent gradual shortening of the refractory period of the affected bundle branch (a phenomenon occasionally referred to as “restitution”), or by the loss of transseptal concealed conduction.

Importantly, acceleration-dependent aberration is a marker of a diseased HPS when it (1) appears at relatively slow heart rates (less than 70 beats/min); (2) displays LBBB (Fig. 10.5); (3) appears after several cycles of accelerated but regular rate; or (4) appears with gradual rather than abrupt acceleration of the heart rate.²

Pause-Dependent Bundle Branch Block

Pause-dependent (or bradycardia-dependent) block occurs when conduction of an impulse is blocked in tissues well after their normal refractory periods have ended. Phase 4 aberration is one explanation for the development of aberration at the end of a long cycle (i.e., after a pause). Phase 4 block is governed by the same physiological principles as those for phase 3 block. Membrane responsiveness is determined by the relationship of the membrane potential at excitation with the maximum rate of rise of phase 0. The availability of the Na⁺ channels is reduced at less negative membrane potentials, and activation at a reduced membrane potential is likely to cause aberration or block. The cause of membrane depolarization (i.e., reduction of membrane potential) in the setting of phase 4 block, however, is different from that in phase 3 block.^{2,4}

Phase 4 or diastolic depolarization is a property of pacemaker cells of the heart; normal His-Purkinje fibers do not possess this property at rates faster than 40 beats/min; however, diseased Purkinje cells can

eFig. 10.2 Premature Ventricular Complexes During Atrial Fibrillation. Several features suggest that the wide QRS complexes are caused by ventricular ectopy rather than aberration. QRS morphology is inconsistent with either left bundle branch block or right bundle branch block aberrancy. Additionally, there is a fixed coupling interval between the normal and aberrant QRS complex. The absence of a long-short cycle sequence associated with the wide QRS complex and the absence of aberrancy despite the presence of R-R cycle length combinations elsewhere in the tracing that are longer and shorter than those associated with the wide QRS complex also suggest ventricular ectopy.

Fig. 10.5 Acceleration-dependent Aberration. The lead II continuous rhythm strip demonstrates sinus rhythm with rate-related left bundle branch block (LBBB). Note that small changes in rate can result in acceleration-dependent aberration. LBBB develops at a sinus rate faster than 70 beats/min, and normal QRS complexes are observed at slower sinus rates. The LBBB and the slow rate at which aberration develops strongly suggest an abnormality in the left bundle branch (LB), rather than physiological aberration, which is often associated with underlying structural heart disease such as cardiomyopathy. Interestingly, the onset and offset of the LBBB demonstrate hysteresis in that the cycle length (CL) required to initiate the LBBB is shorter than the CL required to maintain it, probably because of retrograde concealed penetration of the LB.

Fig. 10.6 Action Potentials in Normal (A) and Diseased (B) Conduction Systems Showing Phase 4 Block. Spontaneous diastolic depolarization during phase 4 in the diseased His-Purkinje system results in reduced availability of sodium channels during the next depolarization, and the resulting action potential cannot propagate the impulse. (From Divakara Menon SM, Ribas CS, Ribas Meneclier CA, Morillo CA. Intermittent atrioventricular block: what is the mechanism? *Heart Rhythm*. 2012;9:154–155, with permission.)

acquire the property of phase 4 depolarization at more rapid rates. Enhanced phase 4 depolarization within the bundle branches can be caused by enhanced automaticity or partial depolarization of injured myocardial tissue. In this setting, the maximum diastolic potential immediately follows repolarization, from which point the membrane potential steadily depolarizes (becomes less negative). This reduction in membrane potential, in turn, causes inactivation of some Na^+ channels. Thus, an action potential initiated early in the cycle (immediately after repolarization) would have a steeper and higher phase 0 and consequently better conduction than would an action potential initiated

later in the cycle when the membrane potential at the time of the stimulus is reduced, with resulting slower upstroke velocity and smaller amplitude of the action potential and, hence, slower conduction or block (Fig. 10.6). Phase 4 aberration is “pause-dependent” because the pause allows for spontaneous depolarization and, hence, the cell is activated from a less negative potential, and the result is impaired conduction (Fig. 10.7). The critical prolongation of the input stimulus is typically initiated by a compensatory pause after a PAC or PVC, spontaneous slowing of the sinus rate, or overdrive suppression of sinus rhythm upon termination of a fast supraventricular rhythm. Once such

Fig. 10.7 Bradycardia-dependent Block. Normal intraventricular conduction is observed during sinus rhythm. Premature atrial complexes (hidden within the T waves) are not conducted to the ventricles, resulting in pauses. The sinus complex following the pause is conducted with left bundle branch block pattern (arrows) presumably secondary to phase 4 block.

critical diastolic membrane potential is reached (at which Na^+ channel inactivation occurs), subsequent conduction may no longer resume until a well-timed escape beat or premature beat (sinus or ectopic) resets the transmembrane potential to its excitable state. The extent of depolarization has to be significant because lesser amounts of depolarization improves excitability (membrane voltage closer to the threshold voltage) and should improve conduction.^{2,5,6}

Despite the fact that bradycardia is common and cells with phase 4 depolarization are abundant, phase 4 block is not commonly seen in normal myocardial tissue. In fact, most reported cases are associated with structural heart disease. One explanation for this phenomenon is that in normal fibers, conduction is well maintained at membrane potentials more negative than -70 to -75 mV. Significant conduction disturbances are first manifested when the membrane potential is less negative than -70 mV at the time of stimulation; local block appears at -65 to -60 mV. Because the threshold potential for normal His-Purkinje fibers is -70 mV, spontaneous firing occurs before the membrane can actually be reduced to the potential necessary for conduction impairment or block. In fact, in the latter setting, mild membrane depolarization can actually improve conduction because the membrane potential is moved closer to threshold potential. Phase 4 block is therefore pathological when it does occur, and it requires one or more of the following: (1) the presence of slow diastolic depolarization, which needs to be enhanced (i.e., occurring at rates faster than these cells normally spontaneously depolarize); (2) a decrease in excitability (a shift in threshold potential toward zero) so that, in the presence of significant bradycardia, sufficient time elapses before a new stimulus arrives, thus enabling the bundle branch fibers to reach a potential at which conduction is impaired; and (3) a deterioration in membrane responsiveness so that significant conduction impairment develops at -75 mV instead of -65 mV; this occurrence would also negate the necessity for such a long cycle before conduction fails. Also, it is important to recognize that, in some cases, pause-dependent aberrancy may be caused by other mechanisms (e.g., source-to-sink mismatch) that may not be related to phase 4 depolarization.^{2,5}

Pause-dependent or phase 4 block almost always manifests an LBBB pattern, likely because the left ventricle (LV) conduction system is more susceptible to ischemic damage and has a higher rate of spontaneous phase 4 depolarization than the right ventricular (RV). Both acceleration-

dependent and pause-dependent aberrancy can be seen in the same patient with an intermediate range of CLs associated with normal conduction. The prognosis of rate-dependent BBB largely depends on the presence and severity of the underlying heart disease. Its clinical implications are not clear, and it usually occurs in diseased tissue and in the setting of myocardial infarction (MI), especially inferior wall MI.⁵

Aberration Caused by Concealed Transseptal Conduction

Concealed transseptal conduction is the underlying mechanism of aberration occurring in several situations, including perpetuation of aberrant conduction during tachyarrhythmias, unexpected persistence of acceleration-dependent aberration, and alternation of aberration during atrial bigeminal rhythm.

Perpetuation of Aberrant Conduction During Tachyarrhythmias

During a supraventricular tachycardia (SVT) with normal ventricular activation, a PVC originating from the RV can retrogradely activate the RB early, whereas retrograde activation of the LB occurs later, following transseptal conduction of the PVC. Consequently, although the RB ERP expires in time for the next SVT impulse, the LB remains refractory because its actual cycle began later than the RB. Therefore the next SVT impulse traveling down the HB encounters an excitable RB and a refractory LB; thus it propagates to the RV over the RB (with an LBBB pattern, phase 3 aberration). Conduction subsequently propagates from the RV across the septum to the LV. By this time, the distal LB has recovered, allowing for retrograde penetration of the LB by the SVT impulse propagating transseptally, thereby rendering the LB refractory to each subsequent SVT impulse (Fig. 10.8). This process is repeated, and the LBBB pattern continues until another well-timed PVC preexcites the LB (and either “peels back” or shortens its refractoriness), so that the next impulse from above finds the LB fully recovered (see Fig. 10.4).²

More commonly, a PAC blocks anterogradely in the proximal portion of the RB to cause RBBB, conducts down the LB to activate the ventricle, crosses the septum to excite the RB retrogradely and make it refractory for the next supraventricular complex, thus perpetuating the RBBB (see below).

Fig. 10.8 Perpetuation of aberrant conduction during supraventricular tachycardia secondary to concealed transseptal conduction. At left, supraventricular tachycardia is associated with normal ventricular activation and narrow QRS complexes. Critically timed ventricular extrastimulus delivered from the right ventricle (*arrow*) precipitates left bundle branch block aberrancy during the tachycardia.

Fig. 10.9 Unexpected Persistence of Acceleration-dependent Aberration. During incremental-rate atrial pacing from the coronary sinus (CS), acceleration-dependent bundle branch block develops at a cycle length (CL) of up to 370 milliseconds. Aberrancy continues despite progressively increasing the pacing CL and disappears only when pacing at a CL of more than 600 milliseconds.

Unexpected Persistence of Acceleration-Dependent Aberration

Acceleration-dependent BBB develops at a critical rate faster than the rate at which it disappears (Fig. 10.9). This paradox is most commonly ascribed to concealed conduction from the contralateral conducting

bundle branch across the septum with delayed activation of the blocked bundle. Such concealed transseptal activation results in a bundle branch-to-bundle (RB-RB or LB-LB) interval shorter than the manifest R-R cycle. The reason is that the actual cycle for the blocked bundle does not begin until approximately halfway through the QRS complex because

it takes 60 to 100 milliseconds for the impulse to propagate down the RB and transeptally reach the blocked LB. Consequently, for normal conduction to resume, the cycle (R-R interval) during deceleration must be longer than the critical cycle during acceleration by at least 60 to 100 milliseconds.²

However, unexpected delay of normalization of conduction cannot always be explained by concealed conduction. Conduction sometimes normalizes with slowing of the heart rate, only to recur at cycles that are still longer than the critical cycle. Such a sequence excludes transeptal concealment as the mechanism of recurrence of the aberration. Similarly, when the discrepancy between the critical cycle and the cycle at which normalization finally occurs is longer than the expected transeptal activation time (approximately 60 milliseconds in the normal heart and 100 milliseconds in the diseased states), transeptal concealment alone cannot explain the delay (see Fig. 10.9). Fatigue and overdrive suppression have been suggested as possible mechanisms of the delayed normalization of conduction.

Alternation of Aberration During Atrial Bigeminal Rhythm

A bigeminal rhythm can be caused by atrial bigeminy, 3:2 AV block, or atrial flutter with alternating 2:1 and 4:1 AV conduction. The alternation can be between a normal QRS complex and BBB or between RBBB and LBBB.

When alternation occurs between a normal QRS complex and RBBB during atrial bigeminy, the ERP of both RB and LB starts simultaneously following the normally conducted PAC, and the ERP of both branches is relatively short because of the preceding short cycle. After the pause, the sinus beat conducts normally, and the ERP of both bundle branches starts simultaneously but is relatively long because of the preceding long cycle. However, because the RB ERP is relatively longer than that of the LB, the next PAC encroaches on the RB refractoriness and conducts with an RBBB pattern (phase 3 block). Subsequently, that PAC is conducted down the LB and across the septum. The PAC activates the RB retrogradely after some delay (concealed transeptal conduction), so that the RB-RB interval (during the following pause) and the RB ERP become shorter. As a result, by the time the next PAC reaches the RB, the RB is fully recovered because of its abbreviated ERP (reflecting the shorter preceding RB-RB interval, which is shorter than the manifest R-R interval during the preceding pause), and normal conduction occurs (see eFig. 10.1).⁷

The same phenomenon (concealed transeptal conduction) explains alternating RBBB and LBBB during bigeminal rhythms. In the presence of RBBB, transeptal concealed conduction from the LB to the RB shortens the RB-RB interval relative to the now longer LB-LB interval. As a result, the ERP of the LB is longer and conduction in the LB fails. In the presence of a refractory LB, conduction propagates through the RB. The delayed transeptal activation of the LB shortens the LB-LB interval. The ERP of the RB is now relatively longer because RB conduction is blocked.

CHRONIC BUNDLE BRANCH BLOCK

Anatomy and Physiology of the His-Purkinje System Cardiac Skeleton

The cardiac skeleton consists of four rings of dense connective tissue that surround the mitral and tricuspid valves and extend to the origins of the aorta and the pulmonary trunk. The aortic valve occupies the central position with the other valve rings attached to it. The right fibrous trigone is formed by the triangular junction between the aortic valve and the medial parts of the tricuspid and mitral valves, and it represents the largest thickening and strongest portion of the cardiac skeleton (see Fig. 9.1). Together with the membranous septum, the

right fibrous trigone constitutes the central fibrous body. The membranous interventricular septum is an inferior extension of the central fibrous body that attaches to the muscular interventricular septum. The membranous septum is crossed on its right aspect by the attachment of the tricuspid valve, dividing the septum into AV and interventricular components. The electrically inert central body and skeleton of the heart functions to electrically isolate the atria from the ventricles, except at the site of penetration of the AV conducting system.

His Bundle

The HB connects with the distal part of the compact AVN and penetrates the central fibrous body (where it is called the “nonbranching” or “penetrating” bundle) in a leftward direction (away from the RA endocardium and toward the crest of the muscular interventricular septum) (eFig. 10.3). The HB then emerges on the crest of the ventricular septum and continues sandwiched between the muscular and the membranous components of the septum for 1 to 2 cm before dividing into the right and left bundle branches. Viewed from the aorta, the HB passes beneath the part of the membranous septum that adjoins the interleaflet fibrous triangle between the right and noncoronary sinuses. The HB is insulated from the atrial myocardium by the membranous septum and from the ventricular myocardium by connective tissue of the central fibrous body, thus preventing atrial impulses from bypassing the AVN. Proximal cells of the penetrating portion are heterogeneous and resemble those of the compact AVN; distal cells are larger, similar to cells in the proximal bundle branches and ventricular myocytes.^{8,9}

Right Bundle

The RB travels as a direct continuation of the HB down the right side of interventricular septum toward the RV apex. The RB is a narrow, cable-like structure, insulated by a fibrous sheath from surrounding myocardium and remains without ramifications for most of its length until it approaches the origin of the right anterior papillary muscle, where it divides profusely into a network of subendocardial fascicles spreading to the RV septal and free walls (see eFig. 10.3). In addition, free-running strands extend from the RB toward the apical trabeculated portion of the RV. The ventricular cavity is also bridged via connections through the moderator band (a muscular structure that crosses from the septum to the RV free wall and supports the anterior papillary muscle of the tricuspid valve). The RB runs subendocardially in its basal and apical thirds and deeper within the muscular portion of the septum in the middle third. This path renders the subendocardial segments vulnerable to stretch and trauma.¹⁰

Left Bundle

The LB at its origin is not a discrete branch of the HB, but arises as numerous fine, intermingling fascicles that leave the left margin of the branching HB through most of its course along the crest of the muscular ventricular septum. The predivisional portion of the LB penetrates the membranous portion of the interventricular septum under the aortic ring and then divides under the septal endocardium into two branches: the left anterior fascicle (LAF) and the left posterior fascicle (LPF). An estimated 65% of individuals have a third fascicle of the LB, the septal or left median fascicle (LMF). The fascicles cascade down the LV septum in a fan-like configuration with extensive interconnections. Unlike the cord-like RB, the LB and its divisions are diffuse, fan-like structures that branch out just beyond their origin (see eFig. 10.3). The LAF represents the superior (anterior) division of the LB, the LPF represents the inferior (posterior) division, and the LMF represents the septal (median) division.⁹

The LB subdivisions extend to the mid portion of the septum before they detach from the underlying endocardium and form free-running

eFig. 10.3 Anatomy of the Atrioventricular Conduction System. (From Netter Images, www.netterimages.com, with permission.)

false tendons that traverse the ventricular chamber, projecting predominantly toward the papillary muscles. The fascicles become ramified in the ventricular apex and extend back along the ventricular walls toward the cardiac base.⁸

The LAF crosses the anterobasal LV region toward the anterior papillary muscle and terminates in the Purkinje system of the anterolateral LV wall. The LPF appears as an extension of the main LB and is large in its initial course. It then fans out extensively toward the posterior papillary muscle and terminates in the Purkinje system of the posteroinferior LV wall. The LMF runs to the interventricular septum; it arises in most cases from the LPF, less frequently from the LAF, or from both, and in a few cases it has an independent origin from the central part of the main LB at the site of its bifurcation.

Purkinje Fibers

The bundle branches and fascicles consist of bundles of Purkinje cells insulated from the surrounding myocardium by a dense sheath of connective tissue. Insulation is lost distally as the Purkinje network connects the ends of the bundle branches to the ventricular myocardium. This design enables the transfer of action potentials to the ventricular apex without activating the ventricular myocardium at the base first, ensuring a synchronized and coordinated apex-to-base contraction pattern that optimizes ventricular ejection.⁸

A combination of subendocardial and free-running Purkinje fibers (false tendons) form complex three-dimensional mesh-like networks on the endocardial surface of both ventricles and penetrate only the inner third of the myocardium. Purkinje fibers tend to be less concentrated at the base of the ventricles and at the tips of the papillary muscle. The free-running false tendons traverse the ventricular chamber and reattach at the free wall myocardium, projecting predominantly toward the papillary muscles. This pattern promotes septal-free wall synchronization.⁸

Cardiac Purkinje cells exhibit structural and electrophysiological (EP) features that are distinct from nodal and working cardiomyocytes. Purkinje fibers are larger than working cardiomyocytes and are more often larger and more rod-shaped than sinus and AV nodal cells. Additionally, Purkinje cells have fewer myofibrils, which are different in composition of myosin from the cells of working myocardium. These myofibrils function only as passive cytoskeletal components. Purkinje cells contain a considerable amount of glycogen, and they exhibit more resistance to hypoxia than the ventricle myocardium cells. As compared to the working ventricular cardiomyocytes, the action potential in Purkinje fibers has a faster upstroke velocity (dV/dt), higher amplitude, more prominent early phase of rapid repolarization (phase 1), more negative plateau potential, and a significantly longer duration.^{11,12}

The Purkinje fiber network is critical for the almost simultaneous depolarization of the terminal HPS and propagation of the cardiac impulse to the entire RV and LV endocardium. Purkinje cells are specialized to conduct rapidly, at 2.3 m/s, much faster than working ventricular cardiomyocytes (0.75 m/s). This rapid conduction is facilitated by the high expression of Na^+ channels, resulting in action potential upstroke velocities of ~ 1000 V/s. Additionally, an exceptionally high enrichment of connexin proteins (Cx40, Cx43, Cx45) result in a very low intercellular resistance (as low as $100 \Omega/cm$). Purkinje fibers are connected to the working myocardial cells by intercalated disks. One Purkinje fiber transfers the impulse to thousands of ventricular cardiomyocytes.^{9,11}

The Purkinje fiber network arrangement guarantees a synchronous action of working cardiomyocytes during the contraction. Ventricular activation starts at the left side of the interventricular septum, followed by a wave of excitation traveling from the apex to the base (to ensure efficient and optimized ejection towards the basally located semilunar outlet valves), and from the endocardium to the epicardium.

Blood Supply

The HB, and predivisional portion of the LB, receive dual blood supply from the septal branches of the anterior and posterior descending coronary arteries. The RB and LAF are supplied by the septal perforating branches of the left anterior descending coronary artery. The LPF is supplied by the conus branch of the right coronary artery in the majority of the cases. Hence, RBBB or LAF block can result from occlusion of the left anterior descending artery, whereas the development of LBBB during acute MI usually indicates occlusion of both the right and the left anterior descending coronary arteries.¹³

Innervation

The AVN and the HB region are innervated by a rich supply of cholinergic and adrenergic fibers, with a density exceeding that found in the ventricular myocardium. Although neither sympathetic stimulation nor vagal stimulation affects normal conduction in the HPS, either can affect abnormal AV conduction.

Pathophysiology of His-Purkinje System Disease

The clinical presentation of conduction disturbances, in order of decreasing incidence, is LAF block, RBBB, LBBB, and LPF block. This rank depends not only on the intrinsic, anatomical and genetically determined differences among branches and fascicles, but also on the manner in which the intraventricular conduction system is exposed to the various pathological processes of the surrounding cardiac structures.

Right Bundle

The RB runs subendocardially in its basal (proximal) and apical (distal) thirds; this path renders the subendocardial segments vulnerable to stretch and trauma. Chronic RBBB pattern can result from three levels of conduction delay in the RV: proximal, distal, or terminal. Proximal RBBB is the most common site of conduction delay. Distal RBBB occurs at the level of the moderator band (or even more distally), and it is an unusual site of conduction delay unless there has been transection of the moderator band during surgery. Terminal RBBB involves the distal conduction system of the RB or, more likely, the ventricular muscle itself, and it can be produced by ventriculotomy or transatrial resection of parietal bands in repair of tetralogy of Fallot. In addition, RBBB can be caused by events in the HB because certain fibers of the HB are organized longitudinally and predestined to activate only one fascicle or bundle branch.¹⁴

RBBB can be an isolated ECG abnormality or associated with structural heart disease. Causes of RBBB include increased RV pressure, RV hypertrophy or dilatation, ischemic heart disease, acute MI, myocarditis, cor pulmonale, acute and chronic pulmonary embolism, hypertension, cardiomyopathies, congenital heart disease, and Lev and Lenègre diseases. Additionally, transient or permanent RBBB can result from mechanical trauma during right heart catheterization or catheter ablation in the vicinity of the RB and is very common following alcohol septal ablation for hypertrophic cardiomyopathy. Interestingly, in some patients with RBBB who are being considered for a pacemaker, pacing the HB eliminates the RBBB and may be the preferred site of pacing.¹⁵

Left Bundle

LBBB is usually caused by ischemic or mechanical factors, and the site of block is typically in the predivisional segment at the junction of the LB and HB. LBBB is usually encountered in patients with structural heart disease involving dilation, hypertrophy, or fibrosis of the LV such as ischemic heart disease, valvular heart disease, and various cardiomyopathies. Also, LBBB can be caused by Lev and Lenègre diseases.

The LAF can be injured by diseases that involve the LV basal septum, the anterior half of the ventricular septum, and the anterolateral LV

wall. Isolated LAF block is the most common type of IVCD seen in acute anterior MI. LAF block can also be a result of hypertension, cardiomyopathies, aortic valve disease, Lev and Lenègre diseases, or spontaneous or surgical closure of ventricular septal defect.¹⁶

In contrast, the LPF is the least vulnerable segment of the whole conduction system because it is short and wide and is located in the inflow tract of the LV, a less turbulent region than the outflow tract. Additionally, the LPF has a dual blood supply, from the anterior and posterior descending coronary arteries. Isolated LPF block is a rare finding, and rather nonspecific for cardiac disease. LPF block is almost always associated with RBBB.¹⁶

Despite ECG anatomical correlates, the site of block producing BBB patterns is not always certain. Conduction delay can be related to disease affecting the main bundle branch or fascicle, the distal conduction system, or even the working myocardium. Furthermore, data suggest that fibers to the RB and LB are already predestined within the HB and that lesions in the HB can produce characteristic BBB patterns. Longitudinal dissociation with asynchronous conduction in the HB can give rise to abnormal patterns of ventricular activation; hence, the conduction problem may not necessarily lie in the individual bundle branch. Moreover, it is not uncommon for intra-Hisian disease to be accompanied by BBB (especially LBBB). Importantly, the problem may not be actual block, because conduction *delay* within the bundle in the range of as little as 10 milliseconds can give rise to an ECG pattern of BBB.

Nonspecific Intraventricular Conduction Disturbances

The pathophysiology of nonspecific IVCD can be related to intraventricular parietal conduction disease (i.e., Purkinje fiber network or the working myocardium) in the presence of a preserved proximal conduction system (the branches of the HB and their main subdivisions). Nonspecific IVCDs can be observed in various cardiomyopathies and postinfarction. Widening of the QRS is also common in patients with significant LV hypertrophy, likely related to the increase in LV myocardial mass to be depolarized as well as an intramyocardial conduction disorder linked to modification in myofibrillar organization and possibly increased myocardial fibrosis. Additionally, patients with true LBBB or RBBB can have superimposed myocardial disease (e.g., infarction) that can alter the ECG pattern and result in a “nonspecific” IVCD pattern.¹⁷

Clinical Significance

BBB can result from either intrinsic conduction system degeneration or an extrinsic insult from a variety of cardiovascular diseases, and the prognosis of BBB is largely related to the presence, type, and severity of the underlying heart disease, and to the possible presence of other conduction disturbances.

Bifascicular block (especially RBBB and LAF block) is the most common ECG pattern preceding complete heart block in adults.¹⁸ Other forms of IVCD precede the bulk of the remaining cases of complete infranodal AV block. The incidence of progression to complete AV block is approximately 2% in asymptomatic patients with an IVCD and approximately 6% in patients with an IVCD and neurological symptoms (e.g., syncope). The risk of AV block is much higher (up to 70%) in patients with alternating BBB (see below).

Patients with BBB have an unusually high incidence of cardiac disease and sudden cardiac death (SCD). The highest incidence of SCD is among patients with LBBB and cardiac disease. However, many SCDs are caused by VT or ventricular fibrillation (VF), do not seem to be related to AV block, and are not prevented by pacemakers (although pacing can potentially relieve symptoms such as syncope). Complete EP testing and ventricular stimulation are therefore necessary in patients with syncope and BBB because VT can be found in up to 30% to 50%

of cases. Although the poor prognosis associated with BBB is related to myocardial dysfunction, heart failure, and VF rather than heart block, symptoms such as syncope are often related to heart block.^{19,20}

The prevalence of RBBB in the general population is estimated at between 0.2% and 0.8%.²¹ The prevalence increases with age and is two to three times higher in men than in women. RBBB has generally been considered a benign finding that does not imply increased risk when found in individuals free of heart disease. However, this has been challenged by two recent reports suggesting an increase in all-cause and cardiac mortality in individuals with RBBB.^{20,21} Additionally, new-onset RBBB does predict a higher rate of coronary artery disease, heart failure, and cardiovascular mortality. When cardiac disease is present, the coexistence of RBBB suggests advanced disease and is an independent predictor of all-cause mortality. In the setting of an acute MI, RBBB is associated with a significant increase in mortality.^{20–22}

The prevalence of LBBB in the general population ranges from 0.2% to 1.1%, and it increases with age (prevalence increases steadily from <1% at age 50 years to 6% by 80 years). In patients with LBBB associated with ischemic heart disease, hypertension, or cardiomyopathy, the prognosis depends on the severity of the underlying heart disease. Nevertheless, among patients with acute MI, cardiomyopathy, and heart failure, the presence of LBBB is associated with a worse prognosis. Additionally, LBBB can cause ventricular dyssynchrony, which can have detrimental effects on patients with LV dysfunction and heart failure. Importantly, the presence of LBBB can represent the first manifestation of a more diffuse myocardial disease; hence, a noninvasive assessment for structural heart disease and ischemia is reasonable in patients with LBBB and no prior heart disease, especially those with known cardiovascular risk factors.¹⁹ Once heart disease is excluded, the presence of isolated LBBB in young healthy individuals seems to carry no adverse prognostic significance.^{20,23}

LAF block is the most common IVCD in the general population (prevalence, 4.5%). Isolated LAF block does not itself imply a risk factor for cardiac mortality or morbidity, and in a healthy population it should be regarded as an incidental ECG finding. The prognosis of LAF block is primarily related to the underlying heart disease. LAF block in the setting of acute MI is probably associated with increased mortality.¹⁶

Isolated LPF block is a rare finding and rather nonspecific for cardiac disease. When present, LPF block is almost always associated with RBBB, in that LPF block and RBBB share cause, pathogenesis, and prognosis. The combination of LPF block and RBBB in acute MI is associated with a high mortality rate (80% to 87%) during the first weeks after the coronary event. Similarly, the risk of progression toward complete AV block (a form of trifascicular block) is also considerable (42%), and approximately 75% of these patients die of pump failure.

ELECTROCARDIOGRAPHIC FEATURES

Bundle Branch Block

The ECG criteria for different types of fascicular blocks and BBB are listed in [Box 10.1](#). The ECG pattern of BBB can represent either complete block or conduction delay (relative to the other fascicles) that produces asynchronous ventricular activation without necessarily implying complete failure of conduction in the diseased fascicle. Therefore, an ECG pattern of complete BBB can have varying degrees or alternate with contralateral complete BBB pattern. These phenomena can be explained by delay, rather than complete block, as the underlying pathophysiological feature of the ECG pattern.¹

BBB leads to prolongation of the QRS duration, the degree of which depends on the severity of the impairment. With complete BBB, the QRS is 120 milliseconds or longer in duration; with incomplete BBB, the QRS duration is 100 to 120 milliseconds. Also, the QRS vector can

BOX 10.1 Electrocardiogram Criteria for Fascicular and Bundle Branch Block

Complete Right Bundle Branch Block

- QRS duration ≥ 120 ms in adults
- Broad, notched secondary R waves (rsr', rsR', or rSR' patterns) in right precordial leads (V_1 and V_2); R' or r' deflection usually wider than the initial R wave; in a minority of patients, a wide and often notched R wave pattern may be seen in lead V_1 and/or V_2
- Wide, deep S waves (QRS pattern) of greater duration than R wave or greater than 40 ms in leads I and V_6
- Normal R wave peak time in leads V_5 and V_6 but >50 ms in lead V_1
- Of the foregoing criteria, the first three should be present to make the diagnosis; when a pure dominant R wave with or without a notch is present in V_1 , criterion 4 should be satisfied

Complete Left Bundle Branch Block

- QRS duration ≥ 120 ms in adults
- Broad notched or slurred R wave in leads I, aVL, V_5 , and V_6 and an occasional RS pattern in V_5 and V_6 attributed to displaced transition of QRS complex
- Absent q waves in leads I, V_5 , and V_6 , but in the lead aVL, a narrow q wave may be present in the absence of myocardial disease
- R wave peak time >60 ms in leads V_5 and V_6 but normal in leads V_1 , V_2 , and V_3 , when small initial r waves can be discerned in the above leads
- ST and T waves usually opposite in direction to QRS
- Positive T wave in leads with upright QRS may be normal (positive concordance)
- Depressed ST segment and/or negative T wave in leads with negative QRS (negative concordance) are abnormal
- Appearance of LBBB may change the mean QRS axis in the frontal plane to the right, to the left, or superiorly, in some cases in a rate-dependent manner

Left Anterior Fascicular Block

- Frontal plane axis between -45 and -90 degrees
- qR pattern in lead aVL
- R wave peak time in lead aVL ≥ 45 ms
- QRS duration <120 ms

Left Posterior Fascicular Block

- Frontal plane axis between 90 and 180 degrees in adults
- rS pattern in leads I and aVL
- qR pattern in leads III and aVF
- QRS duration <120 ms

be altered by BBB, and generally the last component of the QRS vector becomes oriented in the direction of the myocardial region in which depolarization is delayed (i.e., the region that is activated last).

BBB is characteristically associated with secondary repolarization (ST-T) abnormalities (LBBB more so than RBBB). The T wave is typically opposite in polarity to the last deflection of the QRS. This discordance is caused by the altered sequence of repolarization that occurs secondary to altered depolarization. This is often evident mainly in right precordial leads (leads V_1 , V_2 , overlying the RV) in RBBB, and all leads in LBBB since the bulk of ventricular myocardium is served by the LB.

Right Bundle Branch Block

Development of RBBB alters the activation sequence of the RV, whereas the LV is activated normally. Because the LB is not affected, the initial septal activation (the initial 30 milliseconds of the QRS complex), which

depends on the LB, remains normal, occurring from left to right, and results in septal q waves in leads I, aVL, and V_6 and r waves in leads V_1 , V_2 , and aVR. Thus, the Q wave of a prior MI remains unchanged.

Septal activation is followed by activation of the LV (within the subsequent 40 to 60 milliseconds), occurring over the LB in a leftward and posterior vector and resulting in R waves in the leftward leads (I, aVL, and V_6), as well as s (or S) waves in the anterior precordial leads (V_1 and V_2). This appearance is usually similar to that in normal subjects because the LV is normally electrically predominant during this phase of the QRS.¹

The asynchronous depolarization caused by RBBB is primarily manifested in the later portion of the QRS, beyond the first 80 milliseconds. During this time, RV activation spreads slowly by conduction through working muscle fibers rather than the specialized Purkinje system, and it occurs predominantly after activation of the LV has completed. The forces generated by the late, unopposed RV free wall activation result in a terminal rightward and anterior positivity, manifesting as a second positive deflection that can be small (r') or large (R') in the anterior precordial leads (V_1 and V_2) and S waves in the leftward leads (I, aVL, and V_6 ; Fig. 10.10). The QRS axis is unaffected by RBBB; left or right axis deviation can indicate concurrent LAF or LPF block, respectively (see Fig. 10.10).¹⁸

RBBB also results in abnormal repolarization of the RV myocardium. As a result, there are often secondary ST-segment and T-wave changes present in the right precordial leads. The ST segment change is usually small and, when present, is discordant (i.e., has an axis in the opposite direction) to the terminal mean QRS spatial vector. The T wave also tends to be discordant to the terminal conduction disturbance, resulting in inverted T waves in the right precordial leads (where there is a terminal R' wave) and upright T waves in the left precordial leads (where there is a terminal S wave).

The time interval necessary for full depolarization of the ventricular free wall (from the endocardium to the epicardium) beneath any given ECG electrode corresponds to the interval from the beginning of the QRS complex to the time of initial downstroke of the R wave after it has peaked (or to the time of initial upstroke of the S wave after it has reached its nadir). This interval is termed *R wave peak time* (in preference to the term *intrinsicoid deflection*). Normally, the upper limit of normal for R wave peak time is 35 milliseconds in the right precordial leads, and 45 milliseconds in the left precordial leads. In RBBB, the R wave peak time is delayed in the right precordial leads (more than 50 milliseconds).

Atypical RBBB. Atypical RBBB can be caused by attenuation or loss of posterior deflections in the anteroposterior leads, resulting in an rsR', qR, or M-shaped QRS pattern in lead V_1 . This pattern can be a normal variant, a consequence of a gain of mid-temporal anterior forces secondary to RV enlargement or concurrent LAF block, or the result of a loss of posterior forces caused by a posterior wall MI.

Incomplete RBBB. An incomplete RBBB can result from lesser degrees of conduction delay in the RB. The ECG pattern of incomplete RBBB is similar to that of complete RBBB, except that the QRS duration is between 110 and 120 milliseconds (see Fig. 10.10). An RBBB pattern with a QRS duration shorter than 100 milliseconds can be a normal variant, presumably reflecting a slight delay in the terminal posterobasal forces in some individuals.

The ECG pattern of incomplete or complete RBBB in association with a distinct ST segment elevation in the right precordial leads can be observed in the Brugada syndrome. The Brugada ECG pattern, however, is characterized by the absence of a wide terminal S wave in the left lateral leads (I, aVL, V_6) and no broad terminal R wave in lead aVR, findings indicating that true RBBB is not present (see Fig. 31.13).

Fig. 10.10 Surface electrocardiogram of incomplete and complete right bundle branch block and bifascicular block. LAF, Left anterior fascicle; RBBB, right bundle branch block.

Additionally, the ECG manifestations of the Brugada syndrome are often dynamic or concealed and can be unmasked or modulated primarily by Na^+ channel blockers but also during a febrile state or with vagotonic agents.

Left Bundle Branch Block

The normal sequence of ventricular activation is altered dramatically in LBBB. Complete LBBB results in delayed and abnormal activation and diffuse slowing of conduction throughout the LV. During LBBB, activation of the LV originates from the RB in a right-to-left direction, in contrast to the normal situation in which the first part of the LV myocardium to be activated is the septum in a left-to-right direction via a small septal branch of the LB. Thus, LBBB results in reversal of the direction of the initial septal activation sequence (within the initial 30 milliseconds of the QRS complex), with the activation traveling from right to left and from apex to base as well as to the RV free wall. RV activation is typically completed within the first 45 milliseconds of the onset of the QRS, before the onset of LV activation. However, because the septum is a larger structure than the RV free wall, septal activation predominates, eliciting a leftward and usually anterior vector and resulting in loss of the normal small q waves and initiation of a wide, slurred R wave in leads I, aVL, and V_6 and an rS or QS pattern in lead V_1 (Fig. 10.11). As a consequence, Q waves of a prior MI may disappear, and new Q waves can emerge.¹

Following septal activation, LV activation (starting as late as 44 to 58 milliseconds into the QRS) spreads slowly by conduction through working muscle fibers rather than the HPS, with spatial vectors oriented to the left and posteriorly because the LV is a leftward and posterior structure. As a consequence, the delayed LV activation (unopposed by the now completed RV activation) produces large, broad, and notched or slurred R waves (without q or s waves) in the leftward leads (I, aVL, and V_6), with delayed R wave peak time in the left precordial leads (more than 60 milliseconds). The slowing and notching of the mid-QRS portion are caused by slow transseptal conduction. The terminal

activation vector results from depolarization of the anterolateral LV wall that produces a small vector that is also directed to the left and posteriorly.¹

LBBB may cause no shift or variable degrees of left and superior shift of the frontal plane QRS axis. Pronounced left axis deviation can be associated with additional delay in activation in the LV secondary to myocardial disease. Right axis deviation in the setting of LBBB is rare and may be caused by RV hypertrophy or MI. It has been suggested that a superior axis shift may occur in patients with predivisional LBBB with an additional delay in the LAF. A superior axis can also be observed in patients with RV enlargement.²⁴

The altered activation sequence also changes the sequence of repolarization. Both the ST segment and T wave vectors are discordant from the QRS complex.

Importantly, recent evidence has challenged the conventional ECG criteria for complete LBBB. In particular, the threshold of 120 milliseconds for QRS duration seems to be misleading, as experimental studies found that the QRS duration is usually prolonged by 70 to 80 milliseconds with the onset of LBBB, instead of the 40 milliseconds required by the conventional criteria.^{25,26} In fact, endocardial mapping studies have suggested that one-third of patients with “complete LBBB” diagnosed by conventional ECG criteria do not have endocardial activation consistent with LBBB but likely have a combination of LV hypertrophy and LAF block. Hence, more “strict” ECG criteria were proposed, including a terminal negative deflection in lead V_1 , mid-QRS notching/slurring in at least two of the leads V_1 , V_2 , V_5 , V_6 , I, and/or aVL, and a higher cutoff for QRS duration (140 milliseconds or longer for men and 130 milliseconds or longer for women). During true complete LBBB, mid-QRS notching or slurring (beginning after the first 40 milliseconds and ending at approximately two-thirds through the QRS duration) likely corresponds to the time of breakthrough of activation to the LV endocardium (first notch) and then to the LV posterolateral wall epicardium (second notch).²⁷ In a simulations study, these “strict” ECG criteria for LBBB were found to have greater specificity (100% vs.

Fig. 10.11 Surface electrocardiogram of incomplete and complete left bundle branch block (LBBB).

48%) and equivalent sensitivity (100%) in diagnosing complete LBBB as compared to the conventional LBBB criteria.²⁸ These criteria were also found to predict better response to cardiac resynchronization therapy in patients with heart failure.^{23,29}

Atypical LBBB. Several atypical ECG patterns of LBBB have been identified. In a common atypical pattern, RS deflections are present in leads V₅ and V₆, likely secondary to leftward displacement of the precordial transitional zone, which may be caused by cardiac dilatation. In another atypical pattern, the small initial r wave in the right precordial leads is absent and in lead III, mimicking anterior or inferior MI pattern, respectively.

Incomplete LBBB. Incomplete LBBB can result from lesser degrees of conduction delay in the LB. Although LV activation begins abnormally on the right side of the septum (as in the setting of complete LBBB), much of the subsequent LV activation occurs via the normal conduction system. Incomplete LBBB is characterized by the following: (1) QRS duration of 110 to 119 milliseconds; (2) presence of an LV hypertrophy pattern; (3) R wave peak time longer than 60 milliseconds in leads V₄, V₅, and V₆; and (4) absence of q wave in leads I, V₅, and V₆ and frequent replacement by a slurred initial upstroke (pseudo-delta wave) (see Fig. 10.11). This entity can bear an ECG resemblance to a Wolff-Parkinson-White (WPW) ECG pattern secondary to the delayed upstroke of the R wave, although the PR interval is usually short in WPW syndrome, whereas it should be normal in cases of incomplete LBBB.¹

LV hypertrophy is often associated with delayed activation and prolongation of the QRS duration, mimicking complete or incomplete LBBB pattern, even in the absence of conduction abnormalities. However, in contrast to LV hypertrophy, LBBB is characterized by delayed R wave peak time in leads V₅ to V₆ to over 60 milliseconds.

Fascicular Block

Hemiblocks in the LB system affect the LAF, LPF, or LMF. Fascicular block generally does not substantially prolong QRS duration, but alters only the sequence of LV activation. The primary ECG change is a shift in the frontal plane QRS axis because the conduction disturbance primarily involves the early phases of activation. The QRS duration

is usually less than 100 milliseconds (unless complicated by BBB or hypertrophy), although some investigators allow a QRS duration of up to 120 milliseconds, or 20 milliseconds longer than the previous baseline.¹⁶

Left Anterior Fascicular Block

The LAF normally initiates activation in the upper part of the septum, the anterolateral LV free wall, and the left anterior papillary muscle. Delayed activation of these regions secondary to damage to the LAF causes unopposed activation wavefronts by the LPF and LMF early during the QRS complex and unopposed anterosuperior forces late during ventricular activation. All these changes occur with a QRS that widens no more than 20 milliseconds in pure and uncomplicated LAF block.¹⁶

As a consequence, the initial (first 20 milliseconds) QRS vector is normal in time, but it has an abnormal direction. Rather than proceeding superiorly and to the left, the QRS vector depicts an inferior and rightward shift in the frontal plane (frontal plane axis more than +120 degrees) that produces a small, sharp r wave in the inferior leads (II, III, and aVF) and a small q wave in leads I, aVL, V₅, and V₆. Additionally, the inferior and rightward shift in the initial QRS forces can occasionally result in a small, sharp q wave in leads V₂ and V₃ (mimicking old anteroseptal infarction patterns) when the electrodes are placed at the normal level and, in almost all cases, when they are placed in a higher position.¹

During the midportion of the QRS, the main forces of LV activation are oriented superiorly and to the left (frontal plane axis more leftward than -45 or -60 degrees), with a wide-open counterclockwise-rotated loop in the frontal plane caused by the delayed activation of the high lateral wall, which is normally activated by the LAF. This results in deep S waves in leads II, III, and aVF (S wave deeper in lead III than in lead II), and R waves in aVR and aVL. The net effect is an rS pattern in leads II, III, and aVF and a qR or R pattern in leads I, aVL, V₅, and V₆. Additionally, as a result of the superiorly directed forces, deeper S waves are recorded in leads V₅ and V₆; these waves tend to disappear when the electrodes are placed above the normal level and are deeper when the electrodes are placed below the normal level.¹⁶

Of note, the ECG pattern of LAF block can simulate LV hypertrophy in limb leads I and aVL. Conversely, it can conceal signs of LV hypertrophy in the left precordial leads, and it can also hide signs of inferior ischemia.

Left Posterior Fascicular Block

The early unopposed activation of the anterolateral wall of the LV by the normally conducting LAF and LMF causes the initial forces to be oriented superiorly and to the left, producing initial small r waves in leads I, aVL, V₁, and V₆ and small q waves in leads II, III, and aVF. However, the main and terminal forces of the QRS are directed posteriorly, inferiorly, and to the right with a wide-open clockwise-rotated loop, because of the late unopposed activation of the areas normally activated by the LPF (the inferoposterior LV free wall). This is responsible for the characteristic rightward frontal plane axis of +120 to +180 degrees. As a result, there is a qR morphology in leads II, III, and aVF and an rS morphology in leads I and aVL. In fact, the ECG pattern of LPF block is the exact mirror image of LAF block in the standard and unipolar leads. LPF block is almost always associated with RBBB. Isolated LPF block is extremely rare, and a firm diagnosis requires that other causes of right axis deviation have been excluded.^{1,16}

Left Median Fascicular Block

The ECG pattern seen with LMF block is probably determined by the differences in the sites of insertion of the LMF, LAF, and LPF. Functional block in the LMF can lead to the apparent loss of anterior forces and can result in the transient development of q waves in leads V₁ and V₂, which normally have a positive initial deflection caused by septal depolarization. These changes are similar to those that occur in septal MI. On the other hand, prominent R waves are seen in the right precordial leads when LMF block leads to a gain of anterior forces. These changes are similar to those caused by true posterior MI. The prominence of the R waves may be increased when LMF block occurs in association with RBBB.

Other Types of Intraventricular Conduction Abnormalities

Nonspecific Intraventricular Conduction Defects

A nonspecific IVCD is the result of diffuse slowing of impulse conduction involving the entire HPS that causes a generalized and uniform delay in activation of the ventricular myocardium. A nonspecific IVCD is diagnosed in the presence of a QRS duration longer than 120 milliseconds and a QRS morphology that does not resemble either LBBB or RBBB and may even resemble the normal QRS complex. Nonspecific IVCDs can be classified as LV or RV IVCD, depending on the site of delayed R wave peak time and the direction of the terminal forces.¹

Bifascicular Blocks

Bifascicular block refers to different combinations of fascicular block and BBB. Examples of bifascicular block include RBBB with LAF block (most common; see Fig. 10.10), RBBB with LPF block, and LAF block plus LPF block (which manifests as LBBB).

Trifascicular Blocks

Trifascicular block involves conduction delay in the RB and either the main LB or both the LAF and LPF. The resulting ECG pattern depends on the relative degree of conduction delay in the affected fascicles. Ventricular activation starts at the insertion site of the fastest conducting fascicle, with subsequent spread of activation from that site to the remainder of the ventricles. ECG documentation of trifascicular block during 1:1 AV conduction is rare. ECG manifestations of trifascicular block include the following: (1) complete AV block with a slow ven-

tricular escape rhythm with a wide, bizarre QRS; (2) alternating RBBB and LBBB; and (3) fixed RBBB with alternating LAF and LPF block.

The combination of bifascicular block (RBBB plus LAF block, RBBB plus LPF block, or LBBB) with first-degree AV block on the surface ECG (eFig. 10.4) cannot be considered as trifascicular block because the site of AV conduction delay can reside in either the AVN or HPS. Hence, such a pattern can reflect slow conduction in the AVN with concomitant bifascicular block rather than disease in the third fascicle. In such circumstances, the PR interval on the ECG does not appear to be helpful in selecting those individuals with a prolonged His bundle–ventricular (HV) interval because a normal PR interval can easily conceal a significantly prolonged HV interval and a prolonged PR interval can be caused by a prolonged AH interval. However, two criteria can be of value: (1) a short PR interval (less than 160 milliseconds) makes a markedly prolonged HV interval (i.e., more than 100 milliseconds) unlikely; and (2) a markedly prolonged PR interval (more than 300 milliseconds) almost always indicates that at least some of the AV conduction abnormality, if not all, is caused by AVN conduction delay.³⁰

Alternating Bundle Branch Block

Alternating RBBB and LBBB is manifested by QRS complexes with LBBB morphology coexisting with complexes with RBBB morphology (Fig. 10.12). Often, every other complex is an RBBB or LBBB. Spontaneous alternating BBB, especially when associated with a change in the PR interval, represents the most common ominous sign for progression to AV block (Fig. 10.13). In fact, 70% of these patients develop high-grade AV block within weeks of diagnosis. Beat-to-beat alternation is the most concerning, whereas a change in BBB noted on different days is less ominous.

This phenomenon implies instability of the HPS and a disease process involving the HB or bundle branches. In most patients with diffuse HPS disease, delay or block in one of the bundle branches consistently predominates, and alternating BBB is uncommon. The HV interval in alternating BBB is almost universally prolonged and typically varies with the change in BBB. This group has the highest incidence of HV interval exceeding 100 milliseconds. As a rule, AV conduction delay or block can be assumed to be caused by BBB only in the presence of an alternating or intermittent RBBB and LBBB with a changing PR interval. Not infrequently, the bilateral BBB is caused by acceleration-dependent aberration.

Masquerading Bundle Branch Block

Some ECG features can potentially predict the presence of concomitant conduction delay or block in both the RB and LB. The finding of RBBB pattern (with or without LAF block) in the anterior precordial leads with absent S waves in leads I and aVL can be indicative of concomitant conduction delay or block in the LB (a pattern known as “masquerading BBB”). In typical RBBB, the activation of the RV occurs predominantly after activation of the LV has completed. The forces generated by the late, unopposed RV free wall activation manifest as S waves in the leftward leads (I, aVL, and V₆; see Fig. 10.10). Concurrent delay of the activation of the LV due to LBBB may result in disappearance of the S waves in leads I and aVL in patients with RBBB pattern since the late RV activation is no longer “unopposed.” A recent report identified this pattern of bilateral BBB in 1.5% of ECGs with “RBBB pattern,” and it was associated with high risk of AV block or syncope (24%).^{17,18}

Intermittent Bundle Branch Block

Intermittent BBB, either right or left, is diagnosed on the surface ECG when there are occasional QRS complexes with RBBB or LBBB morphology, interspersed with QRS complexes that have a normal morphology. Most often, the intermittent BBB is rate-related (as discussed

eFig. 10.4 Surface electrocardiogram (ECG) of sinus rhythm with first-degree atrioventricular block and bifascicular block (right bundle branch block and left anterior fascicular block). The PR interval is markedly prolonged (480 milliseconds), which suggests that at least some of the atrioventricular conduction delay, if not all, occurs in the atrioventricular node and is not exclusively in the His-Purkinje system. A diagnosis of trifascicular block cannot be made solely based on this ECG.

Fig. 10.12 Alternating Bundle Branch Block During Atrial Fibrillation. Surface electrocardiogram precordial leads during atrial fibrillation. QRS complexes with left bundle branch block configuration are observed mostly at long cycle lengths, and complexes with right bundle branch block configuration are observed mostly at shorter cycle lengths.

previously); thus, the R-R intervals of the QRS complexes manifesting the BBB are shorter when compared with the intervals of the normal QRS complexes. In other cases, there is no rate-related change in the QRS intervals, but the occurrence of the BBB is a random or sporadic event.

ELECTROPHYSIOLOGICAL TESTING

Baseline Intervals

His-Ventricular Interval

The use of multipolar catheters to record distal, middle, and proximal HB potentials can help localize the site of conduction delay or block within the HPS. The value of prolonged HV interval in predicting the risk of AV block is controversial. Studies have shown that an HV interval longer than 70 milliseconds predicts a higher risk of AV block, especially in symptomatic patients. An HV interval exceeding 100 milliseconds identifies a group of patients at a very high risk of AV block (25% over 22 months).¹⁰

In the presence of RBBB with or without additional fascicular block, the HV interval should be normal as long as conduction is unimpaired in the remaining fascicle (eFig. 10.5). However, 50% of patients with RBBB plus LAF block and 75% of those with LBBB have a prolonged HV interval. Thus, in these patients, a prolonged HV interval itself is nonspecific as a predictor of AV block.

In the presence of LBBB, and in the absence of a change in the HB-RB and HB-RV intervals, the HV interval may be slightly prolonged because the earliest site of depolarization on the left side of the septum via the LB precedes activation of the RB by 5 to 15 milliseconds. Therefore an HV interval of up to 60 milliseconds in the presence of LBBB should be considered normal and does not by itself indicate associated RB or HB disease (eFig. 10.6).²³

Of note, catheter manipulation in the LV or RV can inadvertently produce prolongation of the HV interval and varying degrees of AV block or BBB, or both, usually temporarily (see eFigs. 10.5 and 10.6). Complete heart block can occur during right-sided heart catheterization in a patient with preexisting LBBB or during LV catheterization (LV angiography or ablation procedures) in a patient with preexisting RBBB. Among patients with chronic LBBB, the presence of an r wave of more than 1 mm in lead V₁ appears to identify a subgroup at lower risk for complete AV block in response to catheter trauma to the RB. This ECG sign likely suggests intact conduction over the septal fibers of the LB.³¹

Localization of the Site of Block in Right Bundle Branch Block

Measurement of activation times at different areas of the RV (HB, proximal RB, RV apex, and right ventricular outflow tract [RVOT]) can help assess conduction properties of the RB and distinguish between proximal and distal RBBB (Fig. 10.14). With proximal RBBB, recording of the RB potential is not feasible beyond the site of block. Activation of the RV septum occurs via transeptal spread following LV activation. The transeptal activation begins at the apex and then sequentially activates the midanterior wall and base of the RV. Consequently, the mid and apical portions of the RV septum are activated at least 30 milliseconds after the onset of the QRS. This results in prolongation of the ventricular-right ventricular apical (V-RVA) interval (the interval from onset of the surface QRS to RV apical local activation) to more than 30 milliseconds.¹⁰

In the setting of distal RBBB, activation of the HB, proximal RB, and the RV midseptum and apex remains normal. RB potentials persist at the base of the moderator band but disappear at the midanterior wall (where the moderator band normally inserts). Activation of the free wall at the level of the moderator band is delayed, as is the

eFig. 10.5 Catheter-induced His Bundle–Ventricular (HV) Interval Prolongation. Right bundle branch block with a normal HV is present at baseline (*at left*). Prolongation of the HV interval is observed after introducing a mapping catheter into the left ventricle (LV) that traumatized a portion of the His–Purkinje system. The QRS is also slightly different from baseline. *His_{prox}*, Proximal His bundle; *RVA*, right ventricular apex.

eFig. 10.6 Catheter-induced Trauma to the His Bundle. Left bundle branch block (LBBB) and His bundle–ventricular (HV) interval at the upper limit of normal are observed at baseline (*at left*). Manipulation of the His bundle recording catheter results in prolongation of the HV interval. This is not an artifact of the location of His recording, because the PR interval is also prolonged. There is no change in the QRS complex (LBBB pattern), suggesting trauma to the right bundle (RB) or His fibers destined to the RB. *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium.

Fig. 10.13 Alternating Bundle Branch Block During Sinus Rhythm. Continuous Holter three-lead recordings demonstrating sinus rhythm with first-degree atrioventricular (AV) block and right bundle branch block (RBBB) alternating with left bundle branch block (LBBB). Arrows denote sinus P waves, which are commonly masked by the preceding T waves. Note that sinus beats conducted with RBBB are associated with shorter PR intervals compared with those conducted with LBBB. This suggests that conduction delay in the right bundle branch (RBB) is more severe than that in the left bundle branch (LBB); hence, the PR interval is longer when conduction occurs only over the RBB (i.e., with LBBB pattern), but shorter when conduction occurs only over the LBB (i.e., with RBBB pattern). The first sinus P waves to conduct with LBBB (blue arrows) are associated with the longest PR intervals, with subsequent P waves conducting with somewhat shorter PR intervals, resulting in gross irregularity of the QRS complexes despite relatively regular sinus P waves. These findings are suggestive of severe His-Purkinje system disease and high risk for complete AV block.

subsequent activation of the RVOT and the remaining RV. This results in prolongation of the V-RVOT interval, while the V-RVA intervals remain normal (less than 30 milliseconds).

Localization of the Site of Block in Left Bundle Branch Block

Because the LB and its fascicles rapidly fan out over the entire LV, endocardial activation mapping is of limited value for the assessment of conduction properties of the LB. Therefore, for practical reasons, clinical evaluation has primarily focused on the surface ECG pattern and the HV interval.

A common observation in patients with LBBB is a delay in transseptal activation. The pattern in which the LV is activated initially (i.e., the site of breakthrough) as well as the remainder of the LV endocardium and transmural activation depend critically on the nature of the underlying heart disease. The bizarreness of the QRS width and morphology is more a reflection of the underlying LV disease than of the primary conduction disturbance. Patients with normal hearts and those with cardiomyopathy appear to have an intact distal conducting system and,

hence, early engagement and rapid spread throughout the rest of the intramural myocardium. In patients with large infarcts, the bulk of their distal specialized conducting system has been destroyed; consequently, endocardial activation occurs via muscle-to-muscle conduction and thus is much slower.

Diagnostic Maneuvers

Atrial Extrastimulation

Atrial premature stimulation helps determine the ERP of HPS. Normally, the HPS ERP is 450 milliseconds or less and it decreases with decreasing pacing drive CL. Because the AVN functional refractory period usually exceeds the HPS ERP, it can be difficult to evaluate the HPS ERP. Administration of atropine or catecholamines such as epinephrine or isoproterenol can help decrease AVN refractoriness and allow impulses to reach the HPS earlier so that HPS ERP can be determined. A grossly prolonged HPS ERP or a paradoxical increase in the HPS ERP in response to shortening of the pacing drive CL indicates an abnormal HPS and predicts a higher risk for progression to AV block.

Fig. 10.14 Localization of the Site of Block in Right Bundle Branch Block (RBBB). Two complexes from different patients are shown, with proximal (left panel) and distal (right panel) RBBB, distinguished by the interval from QRS onset to right ventricle apical (RVA) recording. *His_{dist}*, Distal His bundle; *His_{mid}*, middle His bundle; *His_{prox}*, proximal His bundle; *RVA*, right ventricular apex; *RVOT*, right ventricular outflow tract.

Fig. 10.15 His-Purkinje System (HPS) Disease. The PR interval is borderline (210 milliseconds), and the His bundle–ventricular (HV) interval is prolonged (75 milliseconds) during normal sinus rhythm (at right). Atrial pacing at a cycle length of 330 milliseconds results in stressing the HPS and further prolonging the HV interval (108 milliseconds). Right bundle branch block also develops during atrial pacing, a finding suggesting slower conduction over the right bundle than the left bundle. *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *PCL*, pacing cycle length.

Atrial Pacing

During incremental-rate atrial pacing, normal shortening of the HPS refractoriness at decreased pacing CLs facilitates 1:1 AV conduction. The development of second- or third-degree AV block within the HPS (in the absence of changing AH intervals) at pacing cycle lengths (PCLs) longer than 400 milliseconds is abnormal and suggests a high risk (50%) for progression to high-grade AV block (Fig. 10.15).

His Bundle Pacing

Selective pacing of the HB can help localize the site of bundle branch block. Normalization of the QRS during HB pacing is suggestive of HB disease proximal to the pacing site (eFig. 10.7).¹⁴

Ventricular Pacing

During RV pacing, retrograde RBBB is characterized by recording the His potential occurring after local ventricular activation in the HB

eFig. 10.7 Left Bundle Branch Block (LBBB) Secondary to Intra-Hisian Disease. Left, electrocardiogram leads and intracardiac recordings in a patient with complete LBBB. Right, pacing from the His bundle (HB) pacing normalizes the QRS complex, a finding suggesting that the LBBB is caused by HB disease proximal to the pacing site. *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle; *NSR*, normal sinus rhythm; *RVA*, right ventricular apex.

Fig. 10.16 Bidirectional right bundle branch block (RBBB). The sinus complex at left has proximal RBBB, indicated by a very prolonged ventricular–right ventricular apical (V–RVA) time (more than 100 milliseconds). RV pacing with the next two complexes show His activation following local ventricular activation in the His bundle (HB) recording, caused by propagation from the RV pacing site across the interventricular septum to the left bundle and then to the HB, rather than the more direct route retrogradely up the right bundle. This is consistent with both anterograde and retrograde proximal RBBB. *His_{dist}*, Distal His bundle; *His_{prox}*, proximal His bundle; *HRA*, high right atrium; *RVA*, right ventricular apex.

region (on the same catheter recording the His potential). The delay in HB activation is secondary to the longer route the paced impulse has to travel to reach the HB. The activation wavefront propagates from the RV pacing site across the interventricular septum to the LB and then to the HB, rather than the more direct retrograde route up the RB, which takes longer time than that required to activate the basal RV septum (Fig. 10.16).

Importantly, assessment of retrograde VH (or VA) conduction is not useful as an indicator of anterograde HPS reserve. Anterograde RBBB is usually proximal, whereas during RV stimulation, block usually occurs at the gate, which is at the distal HPS–myocardial junction.

Procainamide Challenge

The administration of drugs known to impair the HPS (e.g., procainamide) can unmask extraordinary sensitivity to the usual therapeutic doses of the drug, which itself can indicate poor HPS reserve. In normal individuals and in most patients with a moderately increased HV interval (55 to 80 milliseconds), procainamide typically produces a 10% to 20% increase in the HV interval. Abnormal HV interval responses to procainamide representing evidence of a higher risk for infra-Hisian AV block include any of the following: (1) doubling of the HV interval, (2) prolongation of the HV interval to more than 100 milliseconds, or (3) second- or third-degree infra-Hisian block.

Role of Electrophysiological Testing

EP testing is used to obtain information that could predict which patients are at risk for syncope, AV block, or SCD from a ventricular tachyarrhythmia (Box 10.2). Complete EP testing with programmed atrial and ventricular stimulation is necessary in patients with syncope and BBB because VT can be induced in 30% to 50% of such patients. Pacemaker therapy clearly can help prevent syncope in those patients in whom that event most likely was caused by transient bradyarrhythmia, but it has not been shown to prevent SCD or reduce cardiac mortality. The guidelines for permanent pacing therapy in chronic BBB are listed in Box 10.3.

BOX 10.2 Role of Electrophysiological Testing in Patients With Intraventricular Conduction Disturbances

EP Indicators of HPS Disease

- HV interval >55 ms
- Infra-Hisian block at atrial PCL ≥400 ms
- HPS ERP ≥450 ms
- HPS ERPs inversely related to PCLs
- Abnormal response to procainamide: prolongation of the HV interval by 100% or to >100 ms, or second- or third-degree infra-Hisian AV block

EP Indicators of High Risk for AV Block in Patients With IVCD

- HV interval >100 ms
- Infra-Hisian AV block or HV interval prolongation at atrial PCL >400 ms
- HPS-ERPs inversely related to PCLs
- Infra-Hisian AV block or doubling of the HV interval following procainamide in patients with neurological symptoms compatible with bradyarrhythmia

Possible Indications for Pacing in Patients With IVCD

- LBBB, RBBB, IVCD, RBBB + LAF block, or RBBB + LPF block associated with the following: HV interval >100 ms or HV interval = 60–99 ms in the presence of unexplained syncope or presyncope
- Infra-Hisian block at atrial PCL ≥400 ms (regardless of HV interval or presence of symptoms)
- Alternating BBB (regardless of HV interval or presence of symptoms)

AV, Atrioventricular; BBB, bundle branch block; EP, electrophysiological; ERP, effective refractory period; HPS, His-Purkinje system; HV, His bundle–ventricular; IVCD, intraventricular conduction defect; LAF, left anterior fascicle; LBBB, left bundle branch block; LPF, left posterior fascicle; PCL, pacing cycle length; RBBB, right bundle branch block.

BOX 10.3 ACCF/AHA/HRS Recommendations for Permanent Pacing in Chronic Bifascicular Block

Class I

- Advanced second-degree AV block or intermittent third-degree AV block
- Type 2 second-degree AV block
- Alternating bundle branch block

Class IIa

- Syncope not demonstrated to result from AV block, when other likely causes have been excluded, especially ventricular tachycardia
- Incidental finding at EP study of HV interval ≥ 100 ms in asymptomatic patients
- Incidental finding at EP study of pacing-induced block below the bundle of His that is not physiological

Class IIb

- Neuromuscular diseases, such as myotonic muscular dystrophy, Erb dystrophy (limb-girdle muscular dystrophy), and peroneal muscular atrophy with bifascicular block or any fascicular block, with or without symptoms

Class III

- Fascicular block without AV block or symptoms
- Fascicular block with first-degree AV block without symptoms

CLASSIFICATION OF ATRIAL TACHYCARDIAS

Organized atrial tachycardias (ATs) are broadly categorized as either focal (originating from a small circumscribed area from which it spreads out centrifugally) or macroreentrant (continuous, uninterrupted activation wavefront rotating around a relatively large central obstacle).¹

Focal ATs can be caused by automatic, triggered, or microreentrant mechanisms. The mechanism of macroreentrant atrial tachycardia (MRAT) is reentrant activation around a large central obstacle, generally several centimeters in diameter, at least in one of its dimensions. The central obstacle can consist of normal anatomical structures (venous or valvular orifices) or abnormal structures (scars), and can be fixed, functional (anisotropic conduction block), or a combination of both. There is no single point of origin of activation, and atrial tissues outside the circuit are activated from various parts of the circuit (Table 11.1).^{1,2}

Depending on whether the cavotricuspid isthmus (CTI) is critical to the reentry circuit, MRATs are divided into two groups: “CTI-dependent” or “non-CTI-dependent” MRAT. CTI-dependent MRATs include typical atrial flutter (AFL), lower loop reentry, and intra-isthmus reentry.

The term *atrial flutter* has traditionally been used to refer to a continuously undulating pattern on the ECG, without an isoelectric baseline in at least one lead, whatever the cycle length (CL). *Typical AFL* is reserved for a macroreentrant circuit with the activation wavefront rotating clockwise or counterclockwise around the tricuspid annulus

and using the CTI as an essential part of the reentry circuit. *Atypical AFL* is only a descriptive term for an AT with an ECG pattern of continuous undulation of the atrial complex, different from that in typical AFL. However, the term “atypical AFL” introduces unnecessary confusion, and a mechanistic description of the AT circuit in relation to atrial anatomy is preferred (e.g., perimitral macroreentry, lesional right atrial [RA] macroreentry; see Table 11.1).¹

Importantly, classification of ATs based on the 12-lead electrocardiogram (ECG) has been abandoned. Now it is well recognized that the underlying mechanisms of AT, as defined by conventional and advanced mapping techniques, do not correlate well with ECG patterns. Neither the tachycardia rate nor the lack of isoelectric baseline between atrial deflections on the surface ECG is specific for any arrhythmia mechanism.

This chapter discusses focal AT. Typical AFL and MRAT are discussed in subsequent chapters.

PATHOPHYSIOLOGY

Focal AT is characterized by atrial activation starting at a small area (focus), from which it spreads out centrifugally.¹ “Focal” implies that the site of origin cannot be mapped spatially beyond a single point or a few adjacent points with the resolution of a standard 4-mm-tip catheter. In contrast, MRAT is defined by activation that can be recorded over the entire tachycardia cycle length (TCL) around a large central obstacle, which is generally several centimeters in diameter.¹ Relatively

small reentry circuits can resemble focal AT, especially if limited numbers of endocardial recordings are collected (see Fig. 13.11). The term *localized reentry* has been used to refer to reentry in which the circuit is localized to a small area (covering a surface diameter of less than 3 cm) and does not have an easily identifiable central obstacle.

Available information suggests that a focal activation pattern can be caused by automaticity, triggered activity, or microreentry (Table 11.2). Delineating the mechanism of focal AT, however, can be difficult, and the means of distinguishing focal AT mechanisms through pharmacological testing or electrophysiology (EP) study have limited

sensitivity and specificity. In addition, there is a significant overlap in the EP characteristics of tachycardias with differing mechanisms.³ It is especially difficult to discriminate definitively between triggered activity and microreentry as a mechanism of focal AT; therefore some investigators have classified focal ATs as either automatic or nonautomatic.¹ Furthermore, it is not clear that making such mechanistic distinctions among various types of focal ATs carries clinical significance, especially in the era of catheter ablation, although it is possible that such information could be useful in guiding drug therapy. In contrast, determination of the likely focal versus macroreentrant mechanism is critical for planning the mapping and ablation strategy.⁴

Not infrequently, two or more foci of AT can be found in the same patient. In these patients, the AT appears to have different EP characteristics from focal AT with a single focus, as it tends to involve the LA and has greater cardiovascular comorbidity, shorter CL, longer total activation time, and lower acute and long-term success rates of catheter ablation. The term *multiple focal ATs* needs to be distinguished from *multifocal AT* (MAT), which refers to the continuously shifting site of origin of the atrial impulse (see below).⁵

Incessant Atrial Tachycardias

The term *incessant* is applied to an AT that is present for at least 50% of the time that a patient is monitored. Incessant AT frequently is automatic, but it can also be secondary to reentry or triggered activity. Incessant tachycardias occur in up to 25% of patients with focal AT. Foci arising from the atrial appendages and pulmonary veins (PVs) are frequently incessant (84% and 59%, respectively). Incessant ATs (regardless of the anatomical site of origin) can precipitate cardiomyopathy in approximately one-third of cases. Incessant tachycardias precipitating cardiomyopathy characteristically tend to have long atrial CLs as

compared with ATs not associated with cardiomyopathy and hence may produce negligible symptoms and go unrecognized by the patient until symptoms related to cardiomyopathy develop.⁶

Anatomical Locations

Focal ATs have a predilection for originating from certain anatomical regions of the atria (Fig. 11.1).⁷ The RA is the site of origin for the majority (more than 60%) of focal ATs. Approximately two-thirds of RA ATs are distributed along the so-called ring of fire, extending from the superior aspect of the crista terminalis and down the long axis of the crista ("cristal tachycardias"), to the tricuspid annulus, coronary sinus (CS), and atrioventricular (AV) junction, with an apparent gradation in frequency from superior to inferior. This particular anatomical distribution of ATs may be related to the marked anisotropy characterizing the region of the crista terminalis. Such anisotropy, which is related to poor transverse cell-to-cell coupling, favors the development of microreentry by creating regions of slow conduction. Fractionated electrograms often seen at a successful AT ablation site can be markers of the requisite nonuniform anisotropic substrate. In addition, the normal sinus pacemaker complex is distributed along the long axis of the crista terminalis. The presence of automatic tissue, together with relative cellular uncoupling, may be a requirement for abnormal automaticity such that a normal atrium is prevented from electrotonically inhibiting abnormal phase 4 depolarization. Of note, the presence of structural heart disease increases the probability of RA location of the AT, but from sites outside the crista terminalis.

The PV ostia are the most common sites of origin of focal tachycardias within the LA; they account for approximately 67% of LA ATs and between 3% and 29% of all focal ATs.^{7,8} Other sites of tachycardia clustering include the CS os, mitral and tricuspid annuli, bases of right

Fig. 11.1 Anatomical Distribution of Atrial Tachycardias. (A) Common anatomical distribution of focal atrial tachycardias showing rough percentage distribution; the atrioventricular annuli have been removed. (B) Common anatomical distribution of mitral and tricuspid annular atrial tachycardias. AV, Aortic valve; CS (os), coronary sinus (ostium); CT, crista terminalis; HB, His bundle; LAA, left atrial appendage; LPV, left pulmonary veins; MV, mitral valve; RAA, right atrial appendage; RPV, right pulmonary veins; TA, tricuspid annulus; TV, tricuspid valve. (From Lee G, Sanders P, Kalman JM. Catheter ablation of atrial arrhythmias: state of the art. *Lancet* (London, England). 2012;380:1509–1519.)

and left atrial appendages, para-Hisian region, and atrial septum. Focal ATs also can arise within the vein of Marshall, superior vena cava (SVC), or inferior vena cava (IVC). ATs have been described originating from the noncoronary aortic sinus of Valsalva. The distribution of AT foci can differ, depending on the patient population.

A recent report found that the majority of triggered-activity focal ATs originate along the crista terminalis and tricuspid and mitral annuli, whereas automatic ATs often originate from the right or left atrial appendage or PVs. Microreentrant ATs are frequently, but not always, related to previous ablation lines performed for AF or MRAT.⁹

Pulmonary Vein Tachycardia

Arrhythmias originating from the PVs can have a critical role in the development of AF in susceptible individuals. Focal ATs arising from the PVs, however, appear to be a distinct clinical entity from the PV arrhythmias associated with AF. Patients with focal PV ATs do not seem to be at risk of AF in the long term; they resemble patients with focal ATs originating elsewhere with a localized isolated substrate that is successfully addressed with a focal ablative approach. Several potential explanations have been suggested for the different behavior. The underlying pathophysiological process in patients with AF is probably fundamentally different. It is a generalized process diffusely affecting the muscular sleeves in all four PVs, often with multiple PV foci originating distally (up to 2 to 4 cm) within the vein, compared with the focal nature of the process in patients with isolated PV tachycardia. In addition, the CLs of the PV ATs are longer (mean CL 340 milliseconds) than the reported CLs of PV tachycardia in AF patients (130 milliseconds). The CL of AT also tends to be irregular in patients with AF, but not in patients with PV AT. It is possible that foci with shorter CL and irregular activity may not conduct in a 1:1 fashion from the PV to the LA, with resulting fibrillatory conduction and AF. Furthermore, patients with AF tend to be older than those with PV AT and consequently more prone to more widespread atrial remodeling associated with age, hypertension, or other pathological processes.^{3,7}

Multifocal Atrial Tachycardia

MAT (also is known as chaotic AT) is usually caused by enhanced automaticity and is characterized by varying morphology of the P waves, suggesting that the pacemaker arises in different atrial locations (Fig. 11.2). The shift in pacemaker focus is usually associated with different PR intervals (depending on its proximity to the atrioventricular node [AVN]) and varying R-R intervals. The ventricular rate is usually 100 to 130 beats/min but may be as low as 90 beats/min or as high as 250 beats/min. Some P waves can be aberrantly conducted, and some can be nonconducted, further contributing to the irregularity of the ventricular rate.

In general, the ECG diagnosis of MAT requires the following observations: (1) discrete P waves (in distinction to AF); (2) at least three distinctly different P wave morphologies in the same ECG lead (in distinction to focal and MRAT); (3) atrial rate faster than 90 to 100 beats/min (in distinction to wandering pacemaker); (4) absence of one dominant atrial pacemaker (in distinction to normal sinus rhythm [NSR] with frequent premature atrial complexes [PACs]); (5) P waves that are separated by isoelectric intervals (in distinction to AFL); and (6) varying PP, PR, and RR intervals.¹⁰

MAT typically is associated with underlying pulmonary, cardiac, or metabolic disease. In particular, MAT is frequently observed in patients with chronic obstructive pulmonary disease (present in approximately 60% of patients with MAT) or congestive heart failure, especially those treated with theophylline, β -adrenergic agonists, or digoxin, or during a period with exacerbation of the underlying disorder, hypoxemia, or electrolyte imbalance (e.g., hypokalemia, hypomagnesemia, acidosis). MAT can also occur in patients following surgical procedures, especially those with postoperative complications such as respiratory compromise, sepsis, acute heart failure, pulmonary embolism, electrolyte abnormalities, or renal insufficiency. These patients also have higher incidence of other atrial arrhythmias, such as frequent PACs, AF, and AFL.¹⁰

Fig. 11.2 Surface Electrocardiogram of Multifocal Atrial Tachycardia. Note the varying morphology of the P waves and the PR intervals.

MAT does not usually precipitate hemodynamic compromise, and patient's clinical symptoms are primarily related to the underlying illness rather than the tachycardia itself. Hence the management of MAT is mainly directed toward the treatment of the underlying disease, correction of electrolyte abnormalities, and withdrawal of offending drugs (e.g., theophylline, digoxin). IV magnesium can be helpful, even in patients with normal magnesium levels. Pharmacological therapy is associated with limited efficacy in suppressing the arrhythmia and controlling the ventricular rate during MAT. When MAT is symptomatic or leads to decompensation of underlying disease, beta-blockers and verapamil constitute the initial therapy, unless contraindicated because of the presence of bronchospasm or hypotension. Amiodarone can be useful in refractory cases. Electrical cardioversion is not effective and hence not recommended. Catheter ablation is not likely to be effective, given the underlying diffuse atrial abnormalities and severe comorbidities. Ablation of the AVN and pacemaker implantation for rate control is rarely indicated, and should be reserved to patients with severe symptoms related to the tachycardia and failed medical therapy.¹⁰

Sinus Node Reentrant Tachycardia

Sinus node reentrant tachycardia was originally described as a tachycardia that could be induced and terminated by programmed electrical stimulation with a P wave morphology identical or similar to sinus P waves and TCLs of 350 to 550 milliseconds (see Fig. 16.3). There have been some reports of endocardial ablation of sinus node reentrant tachycardias identified by these criteria. However, the precise identification of sinus node reentrant tachycardia remains elusive, and whether the reentry substrate is confined within the sinus node or involves perinodal atrial tissue is unknown, and whether it represents a category distinct from other intraatrial tachycardias is uncertain. More likely, sinus node reentrant tachycardia is a microreentrant focal ATs that happens to be arising along the crista terminalis, very close to the usual location of the sinus node. The arrhythmia typically presents as a paroxysmal tachycardia, and frequently as bursts of nonsustained AT, with P waves that are virtually identical to sinus P waves. Consistent with a reentry mechanism, this tachycardia is usually triggered and terminated abruptly by a PAC. The tachycardia can also be terminated by vagal maneuvers. In contrast to sinus tachycardia, sinus node reentrant tachycardia is characterized by abrupt onset and termination, and often has a longer PR interval than that observed during NSR (since the elevated adrenergic tone that drives the sinus node also accelerates AVN conduction).¹⁰

EPIDEMIOLOGY

Focal atrial ectopy and nonsustained AT are frequently observed on Holter recordings and are seldom associated with symptoms. Sustained focal ATs are relatively infrequent; they are diagnosed in approximately 5% to 15% of patients referred for catheter ablation of supraventricular tachycardia (SVT). However, ATs comprise a progressively greater proportion of paroxysmal SVTs with increasing age, accounting for 23% in patients older than 70 years. Age-related changes in the atrial EP substrate, including cellular coupling and autonomic influences, likely contribute to the increased incidence of AT in older individuals.¹¹ Men and women seem to be equally affected. In adults, focal ATs can occur in the absence of structural heart disease. Nevertheless, the incidence of associated structural heart disease is higher in patients with focal AT than those with other types of paroxysmal SVT. Among focal AT patients, those with multiple tachycardia foci are more likely to have underlying heart disease.¹² The long-term prognosis in patients with focal AT is generally benign, except for those with incessant ATs, which can precipitate tachycardia-induced cardiomyopathy.¹⁰

CLINICAL PRESENTATION

Focal ATs can manifest as paroxysmal or incessant tachycardias. When paroxysmal, AT frequently manifests with episodes of palpitations and heart racing that start and terminate abruptly. Associated symptoms can include lightheadedness, dyspnea, chest discomfort, and weakness. Syncope is rare. Due to the higher prevalence of structural heart disease in this group of patients, symptoms of AT can be more severe than other types of paroxysmal SVTs. Decompensation of underlying heart failure or ischemic heart disease can be precipitated by episodes of AT.

Tachycardia-induced ventricular cardiomyopathy develops in 10% of patients with focal AT, but predominantly in those with incessant or, less commonly, frequently repetitive tachycardia. Incessant AT can precipitate cardiomyopathy in approximately one-third of patients, and frequently manifest with symptoms of congestive heart failure. In contrast to rapid paroxysmal ATs that are more likely to cause significant symptoms of palpitations and be diagnosed earlier in the clinical course, incessant ATs tend to have slower atrial and ventricular rates, and hence patients can remain asymptomatic until they present with decompensated heart failure secondary to tachycardia-induced cardiomyopathy. Elimination of the tachycardia results in normalization of LV function within a few months in the vast majority of patients.⁶

AT can also manifest as a frequently repetitive tachycardia, with frequent episodes of AT interrupted by brief periods of NSR. The repetitive type can be tolerated well for years. It may cause symptoms only in cases of fast heart rates during phases of tachycardia, and it infrequently induces dilated cardiomyopathy.

INITIAL EVALUATION

Clinical symptoms are not usually helpful in distinguishing paroxysmal focal AT from other forms of paroxysmal SVT. Documentation of the arrhythmia during spontaneous symptoms on ECG or ambulatory cardiac monitoring is important to establish the diagnosis. Holter or cardiac event monitoring (depending on the frequency of symptoms) is often adequate. Implantable loop recorders can be helpful in selected cases, with rare episodes associated with severe symptoms of hemodynamic instability (e.g., syncope).

The diagnosis of the incessant and frequently repetitive forms of AT usually can be readily made on ECG recordings based on P wave morphology and the frequent presence of AV block during the tachycardia on ECG recordings. An ECG pattern of AT with discrete P waves and isoelectric intervals is suggestive of a focal mechanism of the AT, but it does not rule out MRAT, especially in patients with complex structural heart disease, prior cardiac surgery for congenital heart disease, or previous AF catheter or surgical ablation. Not infrequently, the diagnosis of focal AT can be established with certainty only by an EP study.

Echocardiography is recommended to exclude or diagnose the presence of structural heart disease. Cardiac stress testing and other diagnostic studies are considered in patients at risk for coronary artery disease.

Invasive EP testing with subsequent catheter ablation can be used for diagnosis and therapy in cases with a clear history of paroxysmal regular palpitations. It can also be considered in patients with preexcitation or disabling symptoms without ECG documentation of an arrhythmia.

PRINCIPLES OF MANAGEMENT

Acute Management

The usual acute therapy for AT consists of IV beta-blockers, diltiazem, or verapamil (Fig. 11.3). However, these drugs have modest efficacy (30% to 50%) in either terminating the focal AT or slowing the

Fig. 11.3 Acute Treatment of Suspected Focal Atrial Tachycardia. Drugs listed alphabetically. ^aFor rhythms that break or recur spontaneously, synchronized cardioversion is not appropriate. IV, Intravenous. (From Page RL, Joglar JA, Caldwell MA, et al. 2015 ACC/AHA/HRS guideline for the management of adult patients with supraventricular tachycardia: a report of the American College of Cardiology/American Heart Association Task Force on Clinical Practice Guidelines and the Heart Rhythm Society. *J Am Coll Cardiol.* 2016;67:e27–e115.)

ventricular rate. Digoxin has not been well studied for focal AT. The response of focal AT to drug therapy is influenced, in part, by the underlying mechanism of the tachycardia. Automatic ATs are more likely to be terminated by beta-blockers, while the response of triggered AT is variable. On the other hand, the response of microreentrant AT can depend on the location of the microreentrant circuit, with those ATs arising from the perinodal region being most sensitive.¹⁰

Vagal maneuvers and adenosine can be used for acute termination of AT. However, ATs can be terminated with vagal maneuvers only on rare occasions, and the response to adenosine is variable. While a significant proportion of triggered ATs will terminate with adenosine, persistence or transient suppression of the tachycardia (with possible transient AV block) is also a common response to adenosine, especially in automatic or microreentrant ATs.¹⁰

For refractory cases, intravenous (IV) ibutilide, class IC drugs (e.g., flecainide, propafenone), or amiodarone can be considered. IV flecainide and propafenone are moderately effective; these agents are not available in the United States. The effectiveness of ibutilide for treatment of focal AT is unclear. IV amiodarone may be reasonable, especially in acute ill patients and those with decompensated heart failure. Electrical cardioversion can be considered for symptomatic patients with drug-resistant arrhythmia. Although electrical cardioversion seldom terminates automatic ATs, it can be successful for triggered and microreentrant ATs.¹⁰

Chronic Management

Long-term therapeutic decisions should consider the severity of symptoms, impact on life style, effectiveness and tolerance of drug therapy, and the presence of concomitant structural heart disease, as well as patient preference (Fig. 11.4).¹⁰

Catheter Ablation

Catheter ablation is recommended in patients with recurrent symptomatic AT, especially when pharmacological therapy is unsuccessful, not tolerated, or not preferred. Catheter ablation is also recommended for incessant AT, even in asymptomatic patients, especially when tachycardia-induced

Fig. 11.4 Ongoing Treatment of Suspected Focal Atrial Tachycardia. Drugs listed alphabetically. *pt*, Patient; *SHD*, structural heart disease (including ischemic heart disease). cardiomyopathy has developed. In the latter group of patients, complete resolution of LV dysfunction has been observed following successful radiofrequency (RF) catheter ablation of the AT focus.⁶ Regardless of whether the arrhythmia is caused by abnormal automaticity, triggered activity, or microreentry, focal AT can be ablated by targeting the site of origin (focus) of the AT. Catheter ablation for focal AT carries a success rate of more than 90%, with a recurrence rate of 9%. The incidence of significant complications is relatively low (1% to 3%) in experienced centers.¹⁰

Pharmacological Therapy

No large studies have been conducted to assess the effect of pharmacological treatment in patients with focal ATs, but both paroxysmal and especially incessant ATs are reported to be difficult to treat medically. Available data support a recommendation for initial therapy with calcium channel blockers or beta-blockers because these agents may prove to be effective and have low side-effect profiles. If these drugs are unsuccessful, then class IC agents (flecainide and propafenone) in combination with an AVN blocking agent, or class III agents (sotalol and amiodarone), may be considered; however, the potential benefit should be balanced by the potential risks of proarrhythmia and toxicity. Because ATs often occur in older patients and in the context of structural heart disease, class IC agents should be used only after cardiomyopathy and coronary artery disease have been excluded.¹⁰

ELECTROCARDIOGRAPHIC FEATURES

P Wave Morphology

During AT, typically there are discrete P waves at rates of 130 to 240 beats/min, but possibly as slow as 100 beats/min or as fast as 300 beats/min. Antiarrhythmic drugs can slow the atrial rate without abolishing the AT. Classically, there are clearly defined isoelectric intervals between the P waves in all leads (Fig. 11.5). However, in the presence of rapid atrial rates or broad P waves due to intraatrial conduction disturbances, there may be no isoelectric baseline. In these cases, the ECG shows an AFL pattern (continuous undulation without isoelectric baseline; Fig. 11.6).¹ Nevertheless, one report demonstrated a high sensitivity (90%) and specificity (90%) of *quantitative* ECG indexes of shorter atrial activation and longer diastolic intervals in distinguishing focal from MRAT. This approach was effective in cases with and without 1:1 AV conduction and when the P or flutter waves overlay T waves.¹³

P wave morphology depends on the anatomical location of the atrial focus, and it can be used to approximate the site of origin of the AT. However, the P wave can be partially masked by the preceding ST segment or T wave. Vagal maneuvers and adenosine infusion to provide transient AV block can be used to obtain a clear view of the P wave, assuming that the tachycardia does not terminate. The compensatory pause following a premature ventricular complex during the AT can also help delineate P wave morphology (Fig. 11.7).

It has been suggested that the multilead body surface potential recording can be used to help localize the site of origin of the tachycardia. One report described a clinical application of ECG imaging (ECGI) as an adjunctive noninvasive technology to identify the site of origin of a focal AT accurately prior to catheter ablation (eFig. 11.1).^{14,15}

Of note, P wave morphology at the onset of the tachycardia can help determine the mechanism of focal AT. Automatic ATs start with a P wave identical to the P wave during the arrhythmia, and the rate generally increases gradually (warms up) over the first few seconds. In comparison, intraatrial reentry or triggered-activity AT is usually initiated by a P wave from a PAC that generally differs in morphology from the P wave during the established arrhythmia (Fig. 11.8).

QRS Morphology

QRS morphology during AT is usually the same as during NSR. However, functional aberration can occur at rapid atrial rates.

P/QRS Relationship

The AV relationship is usually 1:1 during ATs, but Wenckebach or 2:1 AV block (Fig. 11.9) can occur at rapid rates, in the presence of AVN disease, or in the presence of drugs that slow AVN conduction. The presence of AV block during an SVT strongly suggests AT, excludes atrioventricular reentrant tachycardia (AVRT), and renders atrioventricular nodal reentrant tachycardia (AVNRT) unlikely.

ATs usually have a long RP interval; nonetheless, the RP interval can also be short, depending on the degree of AV conduction delay (i.e., PR interval prolongation) during the tachycardia.

Localization of the Tachycardia Site of Origin

P wave morphology on the 12-lead ECG during ATs is determined not only by the anatomical location of the AT focus but also by the subsequent activation pattern within the atrium of origin as well as the contralateral atrium. The activation sequence of the contralateral atrium is determined by the relative proximity of the source of activation to the insertion site of each of the preferential interatrial connections. These include Bachmann's bundle, which connects the anterosuperior RA and LA, the interatrial connection located in the proximity of the CS os, the rim of the fossa ovalis, as well as small muscular bridges connecting the RA posterior wall with the LA posterior wall near the ostia of the right-sided PVs.^{16,17}

The ECG lead V₁ is the most useful in identifying the likely anatomical site of origin for focal AT. Lead V₁ is located to the right and anteriorly in relation to the atria (which should be considered anatomically as right anterior [RA] and left posterior [LA] structures). Thus, for example, tachycardias originating from the tricuspid annulus have negative P waves in lead V₁ because of the anterior and rightward location of this structure (i.e., activation travels *away* from lead V₁). The P wave in lead V₁ is universally positive for tachycardias originating from the PVs because of the posterior location of these structures (i.e., the impulse travels *toward* lead V₁).

In general, P waves identical to the sinus P wave are suggestive of sinus node reentrant tachycardia or perinodal AT. P wave vector in the inferior leads is indicative of the craniocaudal localization of AT origins. Foci in the superior aspect of the atria (such as superior PVs, atrial appendages, and superior crista terminalis) exhibit positive P waves in the inferior leads, whereas those originating from low atrial locations have negative P waves. ATs originating close to the interatrial septum exhibit P waves that are of shorter duration than the sinus P waves. Anterior RA or LA free wall or annular foci tend to have P waves with late precordial transition to an upright appearance. ATs originating from posterior atrial structures (such as the PVs or crista terminalis) usually have positive P waves in the anterior precordial leads.

Several algorithms (Figs. 11.10 and 11.11) have been proposed for ECG localization of focal AT using P wave morphology.⁷ Importantly, while P wave morphology provides a useful guide to the localization of focal AT in patients without structural heart disease, activation patterns can be altered in patients with prior surgery or extensive atrial ablation or in those with significant structural heart disease, significantly rendering P wave morphology significantly less helpful.¹⁸

Right Versus Left Atrial Tachycardias

Several features of P wave morphology can help distinguish RA from LA foci; leads aVL and V₁ are the most helpful for this purpose. In lead V₁, a negative or biphasic (+/−) P wave predicts RA foci with 100%

eFig. 11.1 Noninvasive Electrocardiogram (ECG) Imaging of Focal Atrial Tachycardia (AT). (A) Surface ECG of clinical AT. (B) Isochronal activation map of a basal LAA source centrifugal AT. The morphology of the virtual unipolar electrogram at the source displays typical QS morphology. (C) Intracardiac electrograms from the lateral left atrium and coronary sinus recorded during the ablation of left atrial source centrifugal AT. (D) Posteroanterior fluoroscopic image showing the location of intracardiac catheters. *CSd*, Distal coronary sinus; *CSp*, proximal coronary sinus; *LAA*, Left atrial appendage; *MA*, mitral annulus; *RAA*, right atrial appendage; *RFd*, distal ablation bipole; *RFp*, proximal ablation bipole; *SVC*, superior vena cava; *TA*, tricuspid annulus. (From Shah AJ, Hocini M, Xhaet O, et al. Validation of novel 3-dimensional electrocardiographic mapping of atrial tachycardias by invasive mapping and ablation: a multicenter study. *J Am Coll Cardiol*. 2013;62:889–897.)

Fig. 11.5 Comparison of Focal and Macroreentrant Atrial Tachycardia (AT). (A) Surface electrocardiogram and endocardial activation sequence of focal AT originating from inferior aspect of the mitral annulus with 2:1 atrioventricular (AV) conduction. (B) Surface electrocardiogram and endocardial activation macroreentrant AT around the tricuspid annulus (counterclockwise typical atrial flutter) with 2:1 AV conduction. As illustrated in this case, discrimination between focal and macroreentry as the mechanism of AT based on the presence of distinct isoelectric intervals between the tachycardia P waves can be challenging, caused by superimposition of the QRS and ST-T waves. Endocardial activation (*shaded area*), however, clearly demonstrates that biatrial activation from all electrodes of the 20-pole ("Halo") catheter (around the tricuspid annulus [TA]) and the coronary sinus (CS) catheter occupies only a small fraction (less than 50%) of the tachycardia cycle length (TCL) during focal AT with over half of the TCL without recorded activity. In contrast, biatrial activation occupies most (~90%) of the tachycardia CL during macroreentrant AT. *dist*, Distal; *prox*, proximal.

Fig. 11.6 Surface Electrocardiogram of Focal Atrial Tachycardia Originating From the Right Superior Pulmonary Vein. Second-degree 2:1 atrioventricular block is observed during the tachycardia. Note that the tachycardia in the inferior leads mimics atrial flutter as a result of intraatrial conduction abnormalities as well as overlapping T waves.

Fig. 11.7 Surface Electrocardiogram of Focal Atrial Tachycardia With 2:1 Atrioventricular (AV) Block. Note that every other P wave lies within the QRS, a pattern mimicking supraventricular tachycardia with 1:1 AV conduction. Careful inspection of the whole recording reveals the hidden P waves sometimes occurring at varying timings within the QRS, as indicated by the arrows.

specificity and positive predictive value (sensitivity and negative predictive value in the range of 60% to 70%). Conversely, positive or biphasic (−/+) P waves in lead V₁ predict LA foci with 100% sensitivity and negative predictive value (specificity of 81% and positive predictive value of 76%).^{7,19}

In lead aVL, a positive or biphasic P wave predicts an RA focus with high accuracy (with the exception of right superior PV foci, whereby lead aVL can also exhibit positive P waves). Also, an isoelectric or negative P wave in lead I was 100% specific for an LA focus, but was only present in 50% of patients with LA foci.⁷

Fig. 11.8 Spontaneous Initiation and Termination of a Midseptal Focal Atrial Tachycardia (AT). The tachycardia is initiated and terminated by premature atrial complexes (arrows) of different morphology from that of the AT, a finding suggesting a nonautomatic mechanism. Note the narrow P wave during AT, consistent with a septal origin. *CS_{dist}*, Distal coronary sinus; *CS_{prox}*, proximal coronary sinus; *HRA*, high right atrium; *RVA*, right ventricular apex.

The predictive value of P wave morphology for localizing the atrium of origin is more limited when the tachycardia foci arise from the interatrial septum. Those ATs are associated with variable P wave morphology and considerable overlap for tachycardias located on the left and right sides of the septum.²⁰ As noted, P waves during ATs arising near the septum are generally narrower than those arising in the RA or LA free wall.

Right Atrial Tachycardias

Crista terminalis. Cristal ATs (i.e., ATs arising from the crista terminalis) are characterized by right-to-left activation sequence, resulting in P waves that are positive and broad in leads I and II, positive in lead aVL, and biphasic in lead V₁ (Fig. 11.12). A negative P wave in lead aVR predicts a cristal origin compared with anterior RA foci with a sensitivity of 100% and specificity of 93%. Biphasic (+/−) P waves in lead V₁ (or positive P waves in lead V₁ during both tachycardia and sinus rhythm), positive P waves in leads I and II, and negative P waves in lead aVR predict a cristal origin with 93% sensitivity, 95% specificity, 84% positive predictive value, and 98% negative predictive value.

High, middle, or low cristal locations can be identified by P wave polarity in the inferior leads.¹⁸ ATs originating from the lower crista terminalis exhibit P waves with isoelectric or biphasic patterns in the inferior leads (II, III, and aVF) and positive (but occasionally biphasic [−/+]) pattern in leads V₃–V₆ (eFig. 11.2).^{16,19}

Although there can be an overlap in tachycardia P wave morphology between superior crista (or SVC) foci and the right superior PV foci, due to the close anatomical proximity of these structures, these foci can be distinguished on the basis of changes to the P wave morphology in lead V₁ during tachycardia as compared with sinus P waves. In right superior PV AT, P waves in lead V₁ are invariably upright during tachycardia but can be either upright or biphasic (+/−) in sinus rhythm. When cristal AT has an upright P wave in lead V₁ (approximately 10%), it is invariably also upright during sinus rhythm. The combination of a biphasic or isoelectric P wave polarity in lead V₁ or a biphasic P wave polarity in lead aVL predicts an SVC focus.¹⁷

Anterior septum. In anterosseptal ATs (originating above the membranous septum), the P wave is biphasic or negative in lead V₁. Because of relatively simultaneous biatrial activation, P wave duration is approximately 20 milliseconds narrower than the sinus P wave. Those ATs can

mimic slow-fast AVNRT or orthodromic AVRT utilizing a superoparaseptal bypass tract (BT).

ATs originating in the para-Hisian region (apex of the triangle of Koch) typically exhibit narrow P waves that are consistently positive or isoelectric in leads I and aVL. In the inferior leads, the P wave is negative or biphasic (+/−) in the majority of cases, but can occasionally be positive or biphasic (−/+). In lead V₁, the P wave is typically biphasic, with the dominant positive or negative component opposite to the pattern noted in the inferior leads. The negative inscription of P waves in the inferior leads is likely due to LA activation via CS interatrial connection, while positive P waves suggest activation of the LA via Bachmann's bundle.²¹ In addition, para-Hisian ATs often exhibit a very characteristic narrow and biphasic (−/+) or triphasic (+/−/+) P wave morphology in the precordial leads, especially in V₄ to V₆, and in the inferior leads (eFig. 11.3). Importantly, given the complex anatomical relationship between both sides of the interatrial septum and the aortic root, a P wave morphology consistent with a para-Hisian or anterosseptal location does not accurately predict the successful ablation site (RA, aortomitral continuity, or noncoronary aortic sinus of Valsalva).^{22,23}

Midseptum. Midseptal ATs (originating below the membranous septum and above the CS os) are associated with P waves that are biphasic or negative in lead V₁ and negative in the inferior leads (see eFig. 11.3). Those ATs can mimic fast-intermediate AVNRT or orthodromic AVRT utilizing a midseptal BT.

Posterior septum. In posteroseptal ATs (originating below and around the CS os), the P wave is positive or isoelectric-positive (but occasionally −/+ biphasic) in lead V₁, exclusively negative in the inferior leads (II, III, and aVF), equally positive in leads aVL and aVR, and exclusively negative (but occasionally −/+ biphasic) in all four precordial leads (V₃–V₆). The precordial transition to negativity is variable (see eFig. 11.3). P wave morphology in those ATs can mimic fast-slow AVNRT or orthodromic AVRT using a posteroseptal BT.¹⁶

Tricuspid annulus. A common feature of tricuspid annular ATs is the presence of an inverted P wave in leads V₁ and V₂, with late precordial transition to an upright appearance (see eFig. 11.2). The nonseptal sites demonstrate negative P waves in lead V₁, whereas inferolateral annular sites tend to have inverted P waves across the precordial leads, and superior sites closer to the septum show transition from negative in lead V₁, through biphasic (−/+), to upright in the lateral precordial

P-wave morphology in focal atrial tachycardia: development of an algorithm to predict the anatomic site of origin. *J Am Coll Cardiol*. 2006;48:1010–1017.)

leads. In general, the polarity of leads II and III is deeply negative for an inferolateral annular location and low amplitude, positive, or biphasic for a superior location. In addition, tricuspid annular ATs typically have positive P waves in lead aVL and positive or isoelectric P waves in lead I.¹⁸

In patients with ATs arising from the low RA, P waves that are either exclusively negative or have early negative components in precordial leads V₃–V₆ indicate AT foci at the lower annular aspects of the RA such as the nonseptal tricuspid annulus (6 to 9 o'clock as viewed from the ventricle) and around the CS os, whereas positive P waves in V₃–V₆

Fig. 11.12 Cristal Atrial Tachycardia (AT). Comparison of P wave morphology and endocardial atrial activation sequence between focal AT originating from the crista terminalis (A) and normal sinus rhythm (NSR) (B) in the same patient. A Halo catheter is positioned around the tricuspid annulus (TA). CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus.

predict a low crista terminalis focus. To distinguish ATs of nonseptal tricuspid annular foci from CS os origins, P-wave morphology in leads I and V₁ can be of value. Positive P waves in lead I and negative P waves in lead V₁ suggest nonseptal tricuspid annular foci.¹⁶

RA appendage. Focal ATs originating from the RA appendage typically originate from the lateral base of the appendage but are also well described from an apical location. Because of their close anatomical proximity, these tachycardias are generally indistinguishable from

superior tricuspid annular foci; they exhibit broad, negative, notched P waves in leads V₁ and V₂ and variable precordial transition to positive in lead V₆. P waves in the inferior leads characteristically have low positive amplitudes (see eFig. 11.2).¹⁸

Left Atrial Tachycardias

Pulmonary veins. ATs arising from the PVs are characterized by entirely positive P waves in lead V₁ (in 100% of cases) and across the

precordial leads, isoelectric or negative waves in lead aVL in 86%, and negative waves in lead aVR in 96%. Lead aVL can be biphasic or positive in right-sided PV ATs (eFig. 11.4).⁸

Compared with the right-sided PVs, the left-sided PV foci have several characteristics: positive notching in the P waves in two or more surface leads, an isoelectric or negative P wave in lead I, more positive P waves in lead III than in lead II (P wave amplitude in lead III/II ratio greater than 0.8), and broad P waves in lead V₁ (eFig. 11.5). Right-sided PV foci usually have positive P waves in lead I.

ATs arising from the superior PVs invariably have a positive P wave in the inferior leads. In contrast, ATs arising from the inferior PVs can have inverted, low-amplitude positive, or isoelectric inferior P waves. However, because of the close proximity of the superior and inferior veins and marked anatomical variation, P wave morphology generally is of greater accuracy in distinguishing right-sided from left-sided PVs, in contrast to distinguishing superior from inferior PVs.⁸

ATs arising from the right superior PV are associated with P waves that are narrow and positive in the inferior leads, of equal amplitude in leads II and III, positive in lead V₁, and isoelectric or positive in lead I. The right superior PV is a common site of origin for LA ATs. It is only a few centimeters from the sinus node; hence activation rapidly crosses the septum via Bachmann's bundle to activate the RA in a fashion similar to NSR, a feature explaining the similarities in P wave morphology. However, whereas the P wave is biphasic in lead V₁ during NSR, it is positive in that lead during right superior PV AT (Fig. 11.13).⁸

Despite prior posterior LA ablation, the surface ECG morphology of ATs originating from the PV ostia in patients with prior AF ablation procedures generally is similar to those in patients without prior ablation. However, ATs originating from the bottom of the right or left PVs after prior PV isolation can have a significant negative component or can be completely negative in the inferior leads. This may be related to prior ablation in the superoposterior LA or to a more inferior origin of the tachycardia after prior ablation outside the PV ostium.

LA appendage. In LA appendage ATs, the P wave is positive in the inferior leads (more positive in lead III than in lead II), positive in lead V₁, and deeply negative in leads I and aVL (see eFig. 11.3). The LA appendage closely approximates to the left superior PV, and as such, ATs arising from those locations tend to have similar P wave morphologies. When P wave morphology suggestive of a left superior PV focus (see above), several ECG characteristics suggest an LA appendage origin (reflecting the more anterolateral position of the LA appendage compared with the PVs), including (1) a deeply negative P wave in lead I; (2) negative P waves in leads I and aVL; and (3) upright or biphasic P wave in lead V₁ and isoelectric in leads V₂–V₆. Furthermore, clinical features of the two types of ATs appear to be different; ATs originating from the left superior PV frequently are associated with paroxysmal AF, whereas ATs arising from the LA appendage often present as incessant tachycardias (likely due to an underlying enhanced automaticity mechanism).^{18,17}

Mitral annulus. Mitral annular ATs typically cluster at the superior aspect of the mitral annulus, close to the aortomitral continuity, adjacent to the left fibrous trigone. ATs originating in this circumscribed area are characterized by P waves with an initial narrow negative deflection in lead V₁ followed by a positive deflection. The positivity of the P wave becomes progressively less from lead V₁ through lead V₆. The P wave is negative in leads I and aVL, and isoelectric or slightly positive in the inferior leads (see eFig. 11.3).²⁴

Coronary sinus. ATs arising from the CS musculature typically demonstrate deeply inverted P waves in the inferior leads. P waves are invariably positive in leads aVL and aVR (with greater amplitude in lead aVR). Compared with AT originating from the CS os, ATs

originating from 3 to 4 cm into the body of the CS have broad and positive P waves in lead V₁.¹⁸

Noncoronary aortic sinus of Valsalva. ATs have been described originating from the noncoronary aortic sinus of Valsalva. Because of the close anatomical proximity, the P wave morphology is similar to that of ATs arising from the aortomitral continuity and para-Hisian region (see above). The P waves in leads V₁ and V₂ are usually negative, but biphasic (–/+) P waves in lead V₁ can also be encountered. Unlike aortomitral ATs, those arising from the noncoronary aortic sinus of Valsalva demonstrate positive or isoelectric P waves in leads I and aVL. In the inferior leads, the P waves are low amplitude positive or biphasic (–/+).^{18,21,25}

ELECTROPHYSIOLOGICAL TESTING

Baseline Observations During Sinus Rhythm

The presence of a broad sinus P wave and intraatrial conduction delay suggest atrial disease, which is more prevalent in patients with MRAT, but can still be observed in association with focal AT. Preexcitation, when present, suggests AVRT but does not exclude AT. In addition, the presence of dual AVN physiology suggests AVNRT but does not exclude AT.

Induction of Tachycardia

Frequently, AT foci can become inactive in the EP laboratory environment because of sedative medications, changes in autonomic tone that can be caused by prolonged supine position, patient anxiety, deviation from normal diet, or other changes in daily activities that can have an impact on the circadian variation of AT activity. Thus, in preparation for an AT ablation procedure, several measures should be undertaken. Antiarrhythmic drugs need to be discontinued for at least five half-lives before the EP study. Sedation should be minimized until reproducible inducibility of the arrhythmia is ensured. It may be an appropriate policy to monitor the patient in the EP laboratory initially without sedation. If no spontaneous tachycardia is induced, isoproterenol is administered. If no AT can be induced, a single quadripolar catheter is placed in the RA; and programmed electrical stimulation is performed without and, if no AT is induced, with isoproterenol infusion. If AT remains quiescent, the procedure is aborted and retried at a future date. If AT is inducible at any step, the full EP catheter arrangement and EP study are undertaken (Box 11.1).

Initiation by Programmed Atrial Stimulation

Microentrant AT is usually easy to initiate with a wide range of atrial extrastimulation (AES) coupling intervals (A₁–A₂ intervals). The

BOX 11.1 Programmed Electrical Stimulation Protocol for Electrophysiological Testing of Atrial Tachycardia

Atrial burst pacing from the RA and CS (down to a PCL at which 2:1 atrial capture occurs)
Single and double AES at multiple pacing drive CLs (600–400 msec) from the RA and CS (down to atrial ERP)
Ventricular burst pacing from the RV apex (down to VA Wenckebach CL)
Single and double VES at multiple pacing drive CLs (600–400 msec) from the RV apex (down to ventricular ERP)

AES, Atrial extrastimulation; CL, cycle length; CS, coronary sinus; ERP, effective refractory period; PCL, pacing cycle length; RA, right atrium; RV, right ventricle; VA, ventricular-atrial; VES, ventricular extrastimulation.

Fig. 11.13 Premature Atrial Complexes (PACs) Originating From the Right Superior Pulmonary Vein (PV). (A) 12-lead surface electrocardiogram illustrating atrial couplets during normal sinus rhythm (NSR). Note the similarities in P wave morphology during PACs versus NSR. (B) Intracardiac recordings from the same patient. Detailed mapping localized the origin of the PACs to the ostium of the right superior PV (as illustrated by bipolar and unipolar recordings from the ablation catheter [ABL]). Note the concordance of timing of the bipolar and unipolar recordings and the QS unipolar electrogram morphology (blue arrows), suggesting the site of origin of activation and a good ablation site. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

initiating AES coupling interval and the interval between the initiating AES and first beat of AT are inversely related. Triggered ATs also can be initiated by AES or (more commonly) atrial pacing. However, initiation frequently requires catecholamines (isoproterenol), and, in contrast to microreentrant AT, there is usually a direct relationship between the coupling interval or pacing cycle length (PCL) initiating the AT and the

interval to the onset of the AT and the early CL of the AT. On the other hand, automatic ATs cannot be reproducibly initiated by AES or atrial pacing and are characteristically sensitive to catecholamine stimulation.⁹

In the setting of microreentry and triggered activity, the first tachycardia P wave is different from subsequent P waves; the first P wave is usually a PAC or an AES that is necessary to start the AT (see Fig. 11.8).

Fig. 11.14 Automatic Atrial Tachycardia. Surface electrocardiogram of repetitive nonsustained atrial tachycardia originating from the inferolateral mitral annular region of the left atrium. Note that the first P wave of the tachycardia is similar in morphology to the subsequent P waves, consistent with abnormal automaticity as the mechanism of the tachycardia.

In contrast, the first tachycardia P wave and subsequent P waves during automatic AT are identical; the AT does not require a PAC to start (Fig. 11.14). Furthermore, the automatic TCL tends to shorten progressively (warm up) for several beats until its ultimate rate is achieved.

No delay in the AH or PR interval is required for initiation of AT, although it can occur. AV block can also occur at initiation.

Initiation by Programmed Ventricular Stimulation

It is uncommon to initiate AT with ventricular extrastimulation (VES) or ventricular pacing because decremental retrograde conduction over the AVN prevents adequate prematurity of atrial activation. However, in the presence of an AV BT, fast retrograde atrial activation mediates adequate prematurity of the conducted ventricular stimulus to the atrium, and AT may be induced.

Tachycardia Features

Atrial Activation Sequence

P wave morphology and atrial activation sequence depend on the site of origin of the AT. Intracardiac activation mapping shows significant portions of the TCL without recorded atrial activity, and atrial activation time is markedly less than the TCL (see Fig. 11.5). However, in the presence of extensive atrial scarring or prior ablation, depolarization from the AT focus can occasionally be followed by very disordered and prolonged conduction so that activation of the entire chamber can extend over (or even exceed) the entire TCL, thus mimicking MRAT.²⁶ Conversely, long isoelectric intervals can occur between the P waves during MRATs and can incorrectly suggest a focal mechanism. This pattern is particularly observed for LA MRATs in the presence of large areas of electrical scar or with the use of antiarrhythmic medications. However, in the latter setting, a *thorough* intracardiac activation map reveals atrial activation spanning the TCL. When mapping is limited to only the atrium contralateral to the origin of the macroreentrant circuit or to only parts of the ipsilateral atrium, a focal mechanism can be falsely implied.

Atrial-Ventricular Relationship

The AH and PR intervals during AT are appropriate for the AT rate and are usually longer than those during NSR. They are inversely related: the faster the AT rate, the longer the AH and PR intervals. Thus the PR interval can be shorter than, longer than, or equal to the RP interval.

The PR interval can also be equal to the RR, and the P wave may fall inside the preceding QRS, thus mimicking typical AVNRT.

AV block can be observed during AT because neither the AVN nor the ventricle is part of the AT circuit. Most incessant SVTs with AV block are probably automatic ATs.

Oscillation of the Tachycardia Cycle Length

Oscillation of the ventricular CL occurs frequently during AT and is the result of changes either in the atrial CL or in AVN conduction. When CL variability results from oscillation of the TCL, changes in the atrial CL are expected to precede and predict similar changes in the ventricular CL. On the other hand, ventricular CL variability can be caused by changes in AV conduction instead of changes in the CL of the AT, in which setting ventricular CL variability is not predicted by a prior change in atrial CL. Because there is no VA conduction during AT, ventricular CL variability by itself is not expected to result in subsequent atrial CL variability.²⁷ In addition, spontaneous changes in the PR and RP intervals with fixed A-A intervals favor AT over other types of SVT (Fig. 11.15).

In contrast to AT, typical AVNRT and orthodromic AVRT generally have CL variability caused by changes in anterograde AVN conduction. Because retrograde conduction through a fast AVN pathway or a BT generally is much less variable than the anterograde conduction through the AVN, the changes in ventricular CL that result from variability in anterograde AVN conduction are expected to precede the subsequent changes in atrial CL.²⁷

Large variation in atrial CLs, when present, help distinguish focal AT from MRAT. Variation in the TCL of more than 15% has been suggested as a reliable marker of a focal AT. In contrast, it is rare for MRATs to display considerable variation in the CL. However, a regular AT can be either focal or macroreentrant.

Effects of Bundle Branch Block

Bundle branch block can occur during AT but does not affect the TCL because the ventricles are not participants in AT.

Termination and Response to Physiological and Pharmacological Maneuvers

In the setting of spontaneous termination, ATs terminate with a QRS complex following the last P wave of the tachycardia. Spontaneous

Fig. 11.15 Supraventricular Tachycardia (SVT) With Concentric Atrial Activation Sequence. Note the constant atrial cycle length (*numbers in black*) but variable atrium-to-His bundle interval (*numbers in red*) and ventricular-atrial interval (*numbers in blue*). This observation favors atrial tachycardia (originating from the posteroseptal region) as the mechanism of the tachycardia over other types of SVT. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium.

termination of AT is usually accompanied by progressive prolongation of the A-A interval, with or without changes in AV conduction.

A large proportion (50% to 80%) of focal ATs can be terminated by adenosine; therefore termination of an SVT in response to adenosine is not helpful in differentiating AT from other SVTs. Usually (in 80% of cases), termination of AT in response to adenosine occurs prior to the onset of AV block (i.e., termination occurs with a tachycardia P wave followed by a QRS). Reproducible termination with a P wave not followed by a QRS indicates other types of SVT because it occurs in AT only if adenosine terminates the AT at the same moment it causes AV block, an unlikely coincidence. In the atrium, adenosine produces antiadrenergic effects (presumably responsible for terminating triggered activity) and increases the acetylcholine- or adenosine-activated potassium (K^+) current (I_{KACH}). The results are shortening of the action potential duration and reduction of the resting membrane potential, which may be responsible for terminating atrial microreentry.⁹

The response of focal AT to adenosine can help identify the mechanism of tachycardia. Adenosine does not slow or terminate microreentrant AT. In contrast, triggered activity ATs typically terminate abruptly in response to adenosine and do not spontaneously reinitiate. An automatic AT either is slowed transiently before gradual resumption of the AT rate or is suppressed transiently before spontaneous reinitiation.⁹

Microreentrant ATs can terminate in response to carotid sinus massage and vagal maneuvers. Triggered activity AT also can terminate in response to carotid sinus massage, vagal maneuvers, verapamil, beta-blockers, and sodium channel blockers. During automatic AT, carotid sinus massage can cause AV block and can slow the atrial rate; however, these interventions generally do not terminate the AT. Only beta-blockers have been useful in termination of paroxysmal (but not incessant) automatic AT. Termination of automatic AT is usually preceded by a cool-down phenomenon of the AT rate.

Diagnostic Maneuvers During Tachycardia

Programmed Atrial Stimulation During Tachycardia

Microreentrant atrial tachycardia. AES can reset microreentrant AT with a resetting response classic for reentry (increasing or mixed response). Atrial pacing can entrain microreentrant AT; however, because the microreentrant circuit is very small, only orthodromic capture is usually observed.

Fusion during resetting or entrainment (a hallmark of macroreentrant tachycardias) cannot be demonstrated in microreentrant AT. For atrial fusion (i.e., fusion of atrial activation from both the tachycardia wavefront and the paced wavefront) to occur during resetting or entrainment, the atrial paced impulse should be able to enter the reentrant circuit, while at the same time the tachycardia wavefront should be able to exit the circuit. This requires spatial separation between the entrance and exit sites to the reentrant circuit, a condition that is lacking in the setting of focal AT. Once the tachycardia wavefront exits the reentry circuit to activate the atrium, any atrial stimulus delivered beyond that time and that results in atrial fusion would not be capable of reaching the reentry circuit because the entry-exit site is already refractory as a result of activation by the exiting tachycardia wavefront, and the atrial stimulus has no alternative way to reach the circuit. Similarly, once an atrial stimulus is capable of reaching the reentry circuit, the shared entry-exit site is rendered refractory and incapable of allowing a simultaneous exit of the tachycardia wavefront. Therefore, during entrainment of microreentrant AT by atrial pacing, the atrial activation sequence and P wave morphology are always that of pure paced morphology.

However, it should be recognized that overdrive pacing of a tachycardia of any mechanism (automatic, triggered activity, or microreentrant) can result in a certain degree of fusion, especially when the PCL is only slightly shorter than the TCL. Such fusion, however, is unstable during the same pacing drive at a constant PCL because pacing stimuli

fall on a progressively earlier portion of the tachycardia cycle, thus producing progressively less fusion and more fully paced morphology. Such phenomena should be distinguished from entrainment, and sometimes this requires pacing for many cycles to demonstrate variable degrees of fusion.

During entrainment of microreentrant AT, the return CL and post-pacing interval (PPI) are fixed regardless of the number of beats in the pacing train. AES and atrial pacing can almost always terminate microreentrant AT (especially sinus node reentrant tachycardia).

Triggered-activity AT. AES can reset triggered-activity AT (with a decreasing resetting response). However, triggered-activity AT cannot be entrained by atrial pacing. Following the delivery of an AES or atrial overdrive pacing during triggered-activity AT, the return CL tends to shorten with shortening of the AES coupling interval or PCL. AES and, more effectively, atrial pacing can usually terminate triggered-activity AT.

Automatic AT. The response of automatic AT to AES is similar to that of the sinus node. A late-coupled AES collides with the tachycardia impulse already exiting the AT focus (zone of collision), resulting in fusion of atrial activation (fusion between the paced and the tachycardia wavefronts) or paced-only atrial activation sequence, and it does not affect the timing of the next AT complex (producing a full compensatory pause). An earlier coupled AES enters the AT focus before the time of the next tachycardia wavefront and therefore resets the AT focus (zone of reset), with a return CL that is not fully compensatory. The return cycle usually remains constant over a range of coupling intervals during the zone of reset. A very early coupled AES encounters a refractory AT focus (following the last tachycardia complex) and would not be able to enter or reset the AT focus. Therefore the next AT complex is on time because the atrium is already fully recovered following that early AES (zone of interpolation).

Automatic AT cannot be entrained by atrial pacing; instead, rapid atrial pacing results in overdrive suppression of the AT rate. The AT resumes after cessation of atrial pacing, but at a slower rate, and gradually speeds up (warms up) to return back to prepacing TCL. The tachycardia return CL following cessation progressively prolongs with increasing the duration or rate of the overdrive pacing train. Occasionally overdrive pacing produces no effect at all on automatic AT.

Ventriculoatrial linking. Following cessation of overdrive atrial pacing (with 1:1 AV conduction) during focal AT, the VA interval (the interval between the last captured QRS complex and the first AT complex) can vary significantly from the VA interval during AT because the timing of the AT return cycle is not related to the preceding QRS. In contrast, in the setting of typical AVNRT and orthodromic AVRT, the postpacing VA interval remains fixed and similar to that during tachycardia (with a less than 10-millisecond variation) after different attempts at atrial entrainment of the SVT. VA linking occurs in the setting of typical AVNRT and orthodromic AVRT because the timing of atrial activation is related to or dependent on ventricular activation and is the result of retrograde VA conduction over the AVN fast pathway (during typical AVNRT) or the BT (during orthodromic AVRT).²⁸

Differential-site atrial pacing. Differential-site atrial pacing can help distinguish AT from other mechanisms of SVT. Overdrive pacing is performed during tachycardia from different atrial sites (high right atrium [HRA] and proximal CS) at the same PCL. Once the presence of 1:1 AV conduction during atrial pacing is verified and the SVT resumes following cessation of pacing, the maximal difference in the postpacing VA intervals (the interval from the last captured ventricular electrogram to the earliest atrial electrogram of the initial tachycardia beat after pacing) among the different pacing sites is calculated (Δ VA interval). In one report, a Δ VA interval of more than 14 milliseconds was diagnostic of AT, whereas a Δ VA interval of less than 14 milliseconds

avored AVNRT or orthodromic AVRT (with the sensitivity, specificity, and positive and negative predictive values all equal to 100%). In orthodromic AVRT and AVNRT, the initial atrial complex following cessation of atrial pacing entraining the SVT is linked to, and cannot be dissociated from, the last captured ventricular complex. In contrast, in the setting of AT, the first atrial return cycle following cessation of pacing is dependent on the distance between the AT origin and pacing site, atrial conduction properties, and mode of the resetting response of the AT, and it is not related to the preceding ventricular activation. Hence the postpacing VA intervals vary among the pacing sites, and the Δ VA interval is relatively large (more than 14 milliseconds).²⁸

Variability in PPIs. The global pattern of activation of an atrial arrhythmia can be rapidly determined by comparing the differences in PPIs obtained with overdrive pacing from a single site (proximal CS) at PCLs 10, 20, and 30 milliseconds shorter than the TCL. Relative stability of the PPI, regardless of its relation to the TCL, number of complexes of overdrive pacing or PCL, is highly suggestive of macroreentrant activation of the atrium. High variability of the PPI, on the other hand, is nearly diagnostic of a non-reentrant process. In one report, low PPI variability (less than 10 milliseconds) identified MRATs with a sensitivity of 94% and a specificity of 100%, whereas high PPI variability (more than 30 milliseconds) identified focal ATs with a sensitivity of 93% and a specificity of 100%.²⁹

In macroreentry, the PPI reflects the time required for the stimulated wavefront to travel to a reentrant circuit, revolve once around the circuit, and travel back to the pacing site. Because this distance remains unchanged when pacing from any given site, pacing at faster rates should theoretically not change the distance traveled, and thus the PPI remains stable (PPI variability should approach zero). Faster pacing rates, however, can decrease conduction velocity because of decremental tissue conduction leading to prolongation of the PPI. Nevertheless, this is less likely to occur when overdrive PCLs are limited to within 30 milliseconds of the TCL. In contrast, variability in the PPI is expected in the setting of automatic ATs; by virtue of the phenomenon of overdrive suppression, automatic foci tend to require more time for recovery as pacing rate or duration increases. Unexpectedly, however, large PPI variability was exhibited by all focal ATs regardless of mechanism (including microreentry). By virtue of their small circuits, the microreentrant ATs have a short excitable gap; it is likely that the paced wavefront will penetrate the circuit during relative refractoriness, with decremental conduction resulting in progressive PPI prolongation.²⁹

Programmed Ventricular Stimulation During Tachycardia

It is uncommon for VES or ventricular pacing to affect an AT unless rapid 1:1 VA conduction is present (especially in the presence of an AV BT or enhanced AVN conduction) and the TCL is relatively long.

If ventricular overdrive pacing does not terminate the tachycardia and the presence of stable 1:1 VA conduction during pacing is verified, the electrogram sequence immediately after the last paced ventricular complex is categorized as either an atrial-ventricular (A-V) or atrial-atrial-ventricular (A-A-V) pattern (Fig. 11.16; see detailed discussion in Chapter 20). Following overdrive ventricular pacing (1:1 VA conduction) during AT, retrograde conduction occurs through the AVN. In this setting, the last retrograde P wave resulting from ventricular pacing is unable to conduct back to the ventricle because the AVN is still refractory to anterograde conduction, and the result is an A-A-V response. Conversely, in the setting of AVNRT or orthodromic AVRT, VA conduction occurs through the retrograde limb of the circuit. Therefore, after the last paced ventricular complex, the anterograde limb of the tachycardia circuit is not refractory, and the last entrained retrograde atrial complex can conduct to the ventricle. This results in an A-V response after the last paced QRS (see Fig. 17.19).²⁸

Fig. 11.16 Atrial-Ventricular (A-V) Versus Atrial-Atrial-Ventricular (A-A-V) Response After Ventricular Pacing During Supraventricular Tachycardia (SVT). Overdrive ventricular pacing is performed during five SVTs with concentric atrial activation sequence. Red arrows track ventricular-atrial conduction during ventricular pacing. Numbers indicate ventricular pacing cycle lengths (CLs) and atrial CLs during and after pacing. (A) A-V response is observed following cessation of pacing during typical atrioventricular nodal reentrant tachycardia, which is inconsistent with atrial tachycardia (AT). (B) A-A-V response is observed, consistent with AT originating in the posteroseptal region. CS_{dist}, Distal coronary sinus; CS_{prox}, proximal coronary sinus; HRA, high right atrium; RVA, right ventricular apex.

Importantly, this maneuver is not useful when 1:1 VA conduction during ventricular pacing is absent (Fig. 11.17). In addition, a pseudo-A-A-V response can occur during atypical AVNRT because retrograde conduction during ventricular pacing occurs through the slow pathway (see Fig. 11.17). This can result in a VA interval longer than the PCL; hence the last ventricular paced impulse is followed first by the P wave conducted slowly from the previous paced QRS and then by the P wave resulting from the last paced QRS, thus mimicking an A-A-V response (see Fig. 17.20). Careful identification of the last atrial electrogram that resulted from VA conduction during ventricular pacing avoids this potential pitfall. The last atrial activation resulting from conduction of the last paced ventricular complex follows the preceding P wave with an A-A interval equal to the ventricular PCL.

A pseudo-A-A-V response can also occur during typical AVNRT with long HV intervals or short HA intervals, in which atrial activation precedes ventricular activation. In the latter setting, using His bundle (HB) activation instead of ventricular activation (i.e., characterizing the response as A-A-H or A-H instead of A-A-V or A-V, respectively) can be more accurate and can help eliminate the pseudo-A-A-V response.³⁰

On the other hand, a pseudo-A-V response (Fig. 11.18) can occur with an automatic AT when the maneuver is performed during isoproterenol infusion. Ventricular pacing with 1:1 VA conduction can result in overdrive suppression of the atrial focus, and isoproterenol or epinephrine can cause an increase in junctional automaticity, so that an apparent A-V response occurs. Therefore, when ventricular pacing is performed during catecholamine infusion, it is important to determine that the response after cessation of ventricular pacing is reproducible.²⁸

Diagnostic Maneuvers During Sinus Rhythm After Tachycardia Termination

Atrial Pacing at the Tachycardia Cycle Length

The difference between the AH interval during atrial pacing during NSR at the TCL and that during SVT can help differentiate AT (with long RP interval) from atypical (fast-slow) AVNRT. A ΔAH ($\text{HA}_{\text{pacing}} - \text{AH}_{\text{SVT}}$) greater than 40 milliseconds has been reported to favor fast-slow AVNRT. In contrast, during AT (and orthodromic AVRT utilizing a septal BT), the AH interval during SVT approximates that during atrial pacing. In contrast, a ΔAH of less than 20 milliseconds favors AT and orthodromic AVRT. This criterion has only been tested with RA pacing during RA ATs and should be applied with caution when LA ATs are suspected.³¹

The ΔAH ($\text{AH}_{\text{pacing}} - \text{AH}_{\text{SVT}}$) can also help differentiate typical (slow-fast) AVNRT from AT with a short RP interval. Atrial pacing during NSR at the TCL yields an AH interval that is similar to that during AT but shorter than the AH interval during typical AVNRT. During atrial pacing and AT, AV conduction occurs preferentially over the fast pathway and, hence, is expected to be associated with similar AH and PR intervals (under comparable autonomic tone). In contrast, AV conduction during typical AVNRT occurs over the slow pathway, resulting in a long AH interval.

Ventricular Pacing at the Tachycardia Cycle Length

In the setting of AT (and AVNRT), and under comparable autonomic tone, 1:1 VA conduction over the AVN may or may not be maintained during ventricular pacing at a CL similar to the TCL because of possible retrograde block in the AVN. Anterograde conduction properties of

As noted, the term *localized reentry* has been used to refer to reentry in which the circuit is localized to a small area and does not have a central obstacle. Thus, if activity accounting for more than 85% of the TCL is present in an area with a diameter of up to 3 cm, localized reentry is considered (eFig. 11.6). Fractionated electrograms spanning more than 35% of the TCL often are observed at the site of origin of microreentrant ATs, whereas foci of automatic and triggered-activity focal ATs typically exhibit discrete electrograms.

Reference Electrogram

Determining the onset of the tachycardia P wave is important in activation mapping. The P wave during AT should be assessed using multiple surface ECG leads and choosing the one with the earliest P onset.

eFig. 11.6 Localized Atrial Reentry. Atrial tachycardia had a pattern of activation consistent with emanation from a focus yet could be entrained from multiple sites without evidence of electrocardiogram or intracardiac fusion. Electrogram at ablation site is very prolonged and fractionated, occupying more than 80 milliseconds of tachycardia cycle length (*shaded*), consistent with localized reentry. *Abl_{dist}*, Distal ablation site; *Abl_{prox}*, proximal ablation site; *CS_{dist}*, distal coronary sinus; *CS_{mid}*, middle coronary sinus; *CS_{prox}*, proximal coronary sinus; *TA*, tricuspid annulus.

TABLE 11.5 Exclusion of Macroreentrant Atrial Tachycardia

Parameter	Features
ECG	<ul style="list-style-type: none"> Focal AT usually has a clearly defined isoelectric baseline between P waves in all leads. MRAT usually lacks an isoelectric baseline between deflections.
Atrial activation sequence	<ul style="list-style-type: none"> Focal AT is characterized by atrial activation starting rhythmically at a small area (focus), and intracardiac mapping shows significant portions of the TCL without recorded atrial activity. MRAT endocardial recordings typically show activation spanning the whole TCL.
Programmed electrical stimulation	<ul style="list-style-type: none"> Focal AT is defined on the basis of dissociation of almost the entire atria from the tachycardia with AES. MRAT circuit usually incorporates large portions of the RA or LA, which would be identified with resetting and entrainment mapping.
TCL variability	<ul style="list-style-type: none"> Variation in the TCL of >15% favors focal AT.
Entrainment mapping	<ul style="list-style-type: none"> Automatic and triggered focal AT cannot be entrained. Microreentrant AT can be entrained but with only orthodromic capture. Constant or progressive fusion, as demonstrated by intermediate P wave morphologies on the ECG, cannot be demonstrated. MRAT is defined by demonstration of concealed or manifest entrainment of the tachycardia with atrial pacing.
PPI variability	<ul style="list-style-type: none"> PPI variability of >30 msec favors focal AT. PPI variability of <10 msec favors MRAT.
Electroanatomic mapping	<ul style="list-style-type: none"> Focal AT is suggested by electroanatomic maps demonstrating radial spreading of activation, from the earliest local activation site in all directions, with total activation time \ll TCL. MRAT is suggested by electroanatomic maps demonstrating continuous progression of colors around the RA with close proximity of earliest and latest local activation, with total activation time approximating TCL.
Response to adenosine	<ul style="list-style-type: none"> Focal AT usually responds to adenosine by slowing or termination. MRAT usually is not influenced by adenosine and may actually accelerate (when the TCL is refractoriness-dependent) secondary to shortening of atrial refractoriness by adenosine.

AES, Atrial extrastimulation; AT, atrial tachycardia; CL, cycle length; ECG, electrocardiogram; LA, left atrium; MRAT, macroreentrant atrial tachycardia; PPI, postpacing interval; RA, right atrium; TCL, tachycardia cycle length.

Increasing surface ECG lead gains can help with this determination. However, the P wave can be buried within the preceding T wave or QRS; in this setting, delivering a VES (or a train of ventricular pacing) to accelerate ventricular activation and repolarization during the tachycardia can facilitate visualization of the buried P wave. After determining P wave onset, a surrogate marker that is easier to track during mapping (such as an HRA or CS electrogram) indexed to the P wave onset where it is clearly seen may be used instead of the P wave onset on the surface ECG (eFig. 11.7).

Local Activation Time

A roving catheter is used to find the site, with the earliest atrial electrogram using unipolar and bipolar recordings. Initially, one should seek the general region of the origin of AT/PACs as indicated by the surface ECG and intracardiac recordings in the CS and Halo catheters. Small movements of the catheter tip in the general target region are undertaken under the guidance of fluoroscopy or electroanatomic mapping until the site with the earliest possible atrial activation relative to the P wave is identified. Activation times are generally measured from the onset or the first rapid deflection of the atrial bipolar electrogram to the onset of the P wave or, preferably, surrogate marker during AT. Using the onset of the local bipolar electrogram is preferable, because it is easier to determine reproducibly when measuring heavily fractionated, low-amplitude atrial electrograms. On the recording system display, displaying the intracardiac channel with the earliest local activation timing adjacent to the mapping catheter channel allows the operator to recognize early activation times immediately at sites sequentially visited by the mapping catheter by visual inspection, rather than having to pause and manually measure local activation times. A triggered sweep mode (constant temporal alignment of the display to a reference electrogram) can also be useful for rapid visual assessment of relative timing of mapped sites. The distal pole of the mapping catheter should be the one used for mapping for the earliest atrial activation site because it is the pole through which RF energy is delivered.

Once the site with the earliest bipolar signal is identified, the unipolar signal from the distal ablation electrode should be used to supplement conventional bipolar mapping. The unfiltered (0.05 to >300 Hz) unipolar signal morphology should show a monophasic QS complex with a rapid negative deflection. Although this electrogram configuration is very sensitive for successful ablation sites, it is not specific. The timing of the unipolar electrograms recorded at those sites distant from the AT focus, however, is later than that at the site of origin of the AT. Thus a QS complex should not be the only mapping finding used to guide ablation. Nonetheless, successful ablation is unusual at sites with an RS complex because these are generally distant from the AT focus.

The timing of the unipolar electrograms is also important. Concordance of the timing of the onset of the bipolar electrogram with that of the filtered or unfiltered unipolar electrogram, with the rapid downslope of the S wave of the unipolar QS complex coinciding with the initial peak of the bipolar signal, helps ensure that the tip electrode, which is the ablation electrode, is responsible for the early component of the bipolar electrogram.

The site of origin of the AT is defined as the site with the earliest presystolic (i.e., preceding the onset of the P wave on the surface ECG) bipolar recording, in which the distal tip shows the earliest intrinsic deflection and QS unipolar electrogram configuration (see Fig. 11.13).

Low-amplitude early signals followed by a sharper discrete signal can represent early components of a fragmented electrogram or far-field signal associated with a second discrete local electrogram. This is most likely to happen in regions where separate structures are in close proximity (e.g., superior crista terminalis and right superior PV; LA appendage and left superior PV; RA appendage and superior tricuspid annulus). Unipolar recordings help distinguish far-field from local electrograms. At endocardial sites where the early signal is far field, the unipolar recording fails to exhibit a QS configuration and the sharp negative deflection coincides with the later, high-frequency potential on the bipolar electrogram rather than the earlier far-field signal.

In some cases, several areas can show equivalently early activation, sometimes even with a central area of early local activation time surrounded with areas having later local activation times. This finding can indicate a deeper focus (e.g., in the crista terminalis) or multiple breakthrough sites from a single focus located in an adjacent structure or

eFig. 11.7 P Wave Onset During Atrial Tachycardia (AT) Revealed by Premature Ventricular Stimulation. During AT, P wave onset is difficult to discern (buried in T wave). Double ventricular extrastimuli (S) during AT pull the QRS complexes earlier and allow the P wave to be seen clearly (dark arrow, dashed line). Thereafter, a stable atrial electrogram (e.g., high right atrium [HRA] or proximal coronary sinus [CS_{prox}]) can be used as a surrogate marker for the P wave onset during mapping. CS_{dist}, Distal coronary sinus; CS_{mid}, middle coronary sinus; His_{dist}, distal His bundle; His_{mid}, middle His bundle; His_{prox}, proximal His bundle; RVA, right ventricular apex.

chamber. This can obviously cause confusion during mapping and ablation attempts, with little apparent effect of ablation at a site with very good electrogram characteristics or successful ablation at a site with less optimal parameters. Special attention should be given to ATs mapped to the midseptum and the right anterosseptal region. For ATs

mapped to the midseptum, especially if presystolic activity is not particularly early (i.e., less than 15 milliseconds pre-P wave onset), the electrogram is not fractionated, and multiple sites have similar activation times, exclusion of LA ATs using transseptal access to the LA is important (Fig. 11.19). For ATs mapped to the right anterosseptal region (HB region),

Fig. 11.19 Electroanatomic Activation Map of Focal Atrial Tachycardia Originating From the Anterior Left Atrial (LA) Wall. (A) Left anterior oblique (LAO) view of the CARTO activation map of the right atrium (RA). (B) LAO view of the CARTO activation map of the LA. When mapping is limited to the RA (A), the site of earliest atrial activation was localized to the interatrial septum, with local activation preceding the reference electrogram by 40 milliseconds. When activation mapping is extended to the LA (B), a site with earlier local activation (preceding the reference electrogram by 84 milliseconds) was localized to the anterior LA wall. (C) LAO view of the CARTO activation map of both atria showing that the RA septum activation time is no longer early compared to that of the anterior LA wall. Radiofrequency ablation (*red dots*) at that site eliminated the tachycardia. LAA, Left atrial appendage; LAT, local activation time; MA, mitral annulus; PV, left common pulmonary vein; RSPV, right superior pulmonary vein; TA, tricuspid annulus.

great care must be given to sites in the anteromedial LA septum, right superior PV, aortomitral continuity, noncoronary aortic sinus of Valsalva, and LA free wall, because sites in these regions break through early to the right anterosseptal region, where ablation not only is unsuccessful in eliminating AT but also can result in AV block.

Careful catheter manipulation during mapping should seek to avoid mechanical trauma that can transiently abolish the arrhythmia. Transient catheter-induced interruption of AT by pressure of the catheter can suggest an appropriate site for ablation. This sign is more useful when it is a reproducible phenomenon. Often, however, the tachycardia terminates as the catheter is brushing past the area, and where the catheter comes to rest may not be the same site as where transient AT termination occurred. On the other hand, catheter manipulation frequently induces PACs that can closely mimic target PACs. The findings on the mapping catheter during these catheter-induced complexes are invariably excellent (e.g., substantial presystolic activation time, sharp QS on the unipolar recording). These complexes must be analyzed and carefully compared with prerecorded AT or PAC to avoid delivery of RF energy at sites with no relevance to actual AT.

Tachycardia Transformation

Occasionally, multiple unstable focal ATs or PACs can be encountered during mapping. In this setting, the goal should be to focus mapping on the most frequently encountered AT or PAC. Ablation of the most frequent AT often results in organization of the atria and allows for mapping and ablation of other successive ATs. Importantly, care must be taken to ensure that the correct AT is being mapped and to avoid incorrect sampling of activation times during beats originating from the different foci, which can result in erroneous and confusing activation maps. This can be facilitated by careful attention to changes in P wave morphology or shifting of atrial activation sequences (in the RA or CS), or variations in the TCL during the mapping procedure.

Assessment of simultaneous RA and CS activation sequences by using a multipolar catheter (e.g., duodecapolar or Halo catheters) in the RA around the tricuspid annulus and a decapolar catheter in the CS can facilitate the mapping of ATs. In addition to predicting the anatomic region of interest, it can facilitate recognition of transformation of the index tachycardia to a different morphology induced by catheter manipulation or by pacing maneuvers. This can be especially important when mapping nonsustained AT or PACs.

Right Versus Left Atrial Foci

In addition to P wave morphology on the 12-lead ECG (as noted above), several observations during activation mapping in the RA suggest an LA site of origin the AT, and should prompt consideration for extending the mapping procedure to the LA. First, a distal-to-proximal CS activation sequence is most consistent with LA foci, although ATs originating from the superior RA can result in distal-to-proximal CS activation (especially when the CS catheter is deeply seated into the CS). Importantly, a proximal-to-distal CS activation sequence, although more common during RA AT, can also be observed during ATs originating from the right-sided PVs, LA septum, and aortomitral continuity. Second, when RA mapping localizes the earliest activation site to the superoposterior RA, interatrial septum, or AVN or HB region, an LA site of origin of the AT should be suspected. This is especially true when RA mapping at these sites reveals a relatively large endocardial area with equivalently early local activation times, when the site of earliest local activation is not particularly early, when the unipolar recording at the fails to exhibit a QS configuration, or when the earliest component of the bipolar electrogram is more consistent with far-field recording (i.e., low-amplitude early signal followed by a sharper discrete signal).

Right Atrial Versus Right Superior Pulmonary Vein Foci

AT foci in the region of the right superior PV can quickly propagate to the RA via the closely located Bachmann bundle and posterior-medial interatrial connections. Early activation at the RA breakthrough site(s) usually occurs prior to the P wave onset; as a result, these RA sites can be misdiagnosed during activation mapping as the AT origin.³²

Endocardial atrial activation sequences from the RA, HB, and CS catheters can help predict the location of PAC or AT foci in the SVC or superior RA versus the right superior PV. In one report, the difference in *interatrial* conduction time (between the HRA and distal CS [CS_{dist}] recording electrodes) during NSR versus PAC ($[HRA - CS_{dist}]_{NSR-PAC}$) was significantly longer for right superior PV tachycardias compared with SVC tachycardias. A cutoff value of 20 milliseconds or more of the difference in *interatrial* conduction time could reliably differentiate between both locations. During AT originating from the SVC or superior RA, the tachycardia wavefront activates the RA in a high-low sequence and at the same time propagates through the interatrial connection to the LA, similar to the activation pathway in NSR. As a consequence, there is little change in the interatrial conduction time compared with that during NSR. Conversely, during right superior PV tachycardias, after leaving the vein and entering the LA, the tachycardia wavefront travels to the rest of the LA and simultaneously crosses the interatrial septum to activate the RA. Thus the interatrial conduction time would be much shorter than that during NSR. As a consequence, the difference of interatrial conduction time ($[HRA - CS_{dist}]_{NSR-PAC}$) between the two groups of tachycardias can be a useful prospective method to define the sources of tachycardia before attempting atrial transseptal puncture.³³

Similarly, analyzing *intraatrial* conduction times can facilitate the distinction between PACs or ATs originating from the SVC and high crista terminalis from PV foci. The time interval between HRA and HB atrial activation during PACs originating from the SVC and crista terminalis is significantly longer than that of the sinus beats. A difference in intraatrial conduction time ($[HRA - HB]_{NSR-PAC}$) of less than 0 milliseconds favors SVC or crista terminalis origin. The increased intraatrial conduction delay between HRA and HB recording electrodes is a physiological response to the PACs from the SVC and crista terminalis in the human atrium. In contrast, intraatrial conduction time between the HRA and HB electrodes is shortened in the setting of PV tachycardias because both locations are activated in parallel during PV tachycardias, but in sequence during NSR.³³

Pace Mapping

When atrial activation originates from a point-like source, such as during focal AT or during pacing from an electrode catheter, the resultant P wave recorded on the surface ECG is determined by the sequence of atrial activation, which depends to a large extent on the initial site of myocardial depolarization. In addition, analysis of specific P wave configurations in multiple leads allows estimation of the pacing site location to within several square centimeters. Therefore comparing the paced P wave configuration with that of AT is particularly useful for locating a small arrhythmia focus in a structurally normal heart.

Pace mapping involves pacing from the distal tip of the mapping catheter at sites of interest. Initially, the exact morphology of the tachycardia complex should be determined and used as a template for pace mapping. Pace mapping during the tachycardia (at a PCL 20 to 40 milliseconds shorter than the TCL) is preferable whenever possible because it facilitates rapid comparison of tachycardia and paced complexes at the end of the pacing train. If sustained tachycardia cannot be induced, mapping is performed during spontaneous nonsustained runs or ectopic beats. Although it is preferable to match the PCL and coupling intervals of AESs to those of spontaneous tachycardia or PACs, some reports have suggested that this is not mandatory. Pace mapping is preferably

performed with unipolar stimuli (up to 10 mA, 2 milliseconds) from the distal electrode of the mapping catheter (cathode) and an electrode in the IVC (anode), or with closely spaced bipolar pacing at twice the diastolic threshold, to eliminate far-field stimulation effects.

The greater the degree of concordance between the morphology during pacing and that during tachycardia, the closer the catheter will be to the site of origin of the tachycardia. Pace maps with identical or nearly identical matches of the tachycardia morphology in all 12 surface ECG leads and intracardiac atrial electrograms can be indicative of the site of origin of the tachycardia (Fig. 11.20).

Pace mapping is used as an adjunct to other methods of mapping to corroborate putative ablation sites. It can be of great help, especially when the AT is difficult to induce. However, difficulties in precisely comparing P wave morphologies (low P wave amplitude and superimposition of the P wave on T wave during tachycardia) limit the applicability of pace mapping. Moreover, the spatial resolution of atrial pace mapping is up to 2 cm, which is too imprecise. Utilization of intracardiac activation sequences on multiple catheters (e.g., Halo and CS catheters) can help mitigate those limitations.³⁴ Despite those limitations, many studies have demonstrated efficacy using pace mapping to choose ablation target sites; concordance of P wave morphology during pace mapping and AT has a sensitivity of 86% and a specificity of 37%.

Mapping Postpacing Intervals

Following overdrive atrial pacing from a given site during a relatively regular and stable focal AT, the PPI represents the sum of the conduction time to reach the tissue around the AT focus (perifocal tissue) plus the time required to penetrate the perifocal tissue and reset the focus, plus the TCL, plus the conduction back to the pacing site. Hence if the

pacing site is directly at the AT focus, the PPI should be equivalent to the TCL because of the minimal conduction time between the pacing site and the AT focus. Conversely, pacing at sites distant from the AT focus results in a PPI that is longer than the TCL because of the additional conduction delay between the pacing site and the focus. The difference between the PPI and TCL ($PPI - TCL$) after atrial overdrive pacing of a focal AT was found to have a direct relationship with proximity to the focus, regardless of whether the tachycardia could be entrained. The ($PPI - TCL$) difference approaches zero (and is no more than 20 milliseconds) when pacing directly at the focus of the tachycardia. There appears to be no significant overdrive suppression or acceleration of the AT when pacing at a rate just faster than the AT rate, regardless of the underlying AT mechanism. Therefore the ($PPI - TCL$) difference can be a useful adjunct to localize the AT focus and guide successful ablation sites.³⁵ One must use this technique with caution, since overdrive suppression (that could itself increase the [$PPI - TCL$] difference) is accentuated by pacing for longer durations and/or shorter PCLs. Therefore pacing at a constant PCL, for a similar number of stimuli, from a variety of sites must be used to derive helpful information from this strategy.

In addition, the ($PPI - TCL$) difference can be valuable in distinguishing AT in close proximity to the sinus node from sinus tachycardia. It appears that AT foci, unlike the sinus node, have minimal perifocal conduction delay. Consequently, the ($PPI - TCL$) difference in the setting of focal AT is determined predominantly by the distance from the focus with minimal contribution of the time required to traverse any perifocal tissue, thus explaining the finding that the ($PPI - TCL$) difference approaches zero when pacing is performed directly at the AT focus. In contrast, overdrive pacing during sinus tachycardia is associated with

Fig. 11.20 Pace Mapping of Focal Atrial Tachycardia (AT). Surface electrocardiogram (ECG) (A) and intracardiac recordings (B) demonstrating pace mapping performed during sustained focal AT originating from the interatrial septum. Atrial pacing (left aspect of the ECG and intracardiac recordings) is performed during the tachycardia at a cycle length (CL) of 270 milliseconds from the site of earliest activation (recorded by the Halo catheter positioned around the tricuspid annulus [TA]). Concordance between paced (at the left aspect of the ECG and intracardiac recordings) and tachycardia (at the right aspect of the ECG and intracardiac recordings) P wave morphology on the surface ECG, as well as an endocardial atrial activation sequence, suggests proximity of the pacing site to the AT focus. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus.

a PPI that always exceeds (by more than 80 milliseconds) the sinus CL, even when pacing is performed directly at the origin of the sinus impulse. This finding suggests significant perinodal conduction delay. The (PPI – TCL) difference can therefore be used to distinguish perinodal focal AT from sinus tachycardia.³⁵

Electroanatomic Mapping

Mapping Technique

Mapping of focal AT or PACs is typically performed in conjunction of electroanatomic mapping (CARTO, Biosense Webster, Diamond Bar, CA, United States; EnSite NavX, St. Jude Medical, St. Paul, MN, United States; or Rhythmia, Boston Scientific, San Jose, CA, United States). Activation mapping may be performed by point-by-point mapping with a standard mapping/ablation catheter, a high-density multielectrode mapping catheter (e.g., PentaRay, Biosense Webster), or multielectrode arrays.³⁶

Initially, selection of the reference electrogram, positioning of the anatomical reference, and determination of the window of interest are undertaken. This is the fiducial marker on which the entire mapping procedure is based. The reference catheter is usually placed in the CS (because of its stability) by using an electrode recording a prominent atrial electrogram and ensuring that the ventricular electrogram is not the one picked up by the system.³⁷

The mapping-ablation catheter is initially positioned, using fluoroscopy, at known anatomical points that serve as landmarks for the electroanatomic map. Anatomical and EP landmarks (IVC, SVC, CS, HB, and tricuspid annulus for RA mapping and the mitral annulus and PVs for LA mapping) are tagged. The catheter is then advanced slowly around the chamber walls to sample multiple points along the endocardium, thus sequentially acquiring the location of its tip together with the local electrogram (see Fig. 11.19).

Activation mapping is performed to define the atrial activation sequence. The principles used for conventional activation mapping discussed above are also used here to define the site of origin of AT. A reasonable number of points homogeneously distributed in the RA or LA, or both, must be recorded (approximately 80 to 100 points). The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed intracardiac electrogram obtained from the reference catheter. Points are added to the map only if stability criteria in space and local activation time requirements are met. The activation map can also be used to catalog sites at which pacing maneuvers are performed during assessment of the tachycardia (e.g., sites with good pace maps).

Activation maps display the local activation time by a color-coded overlay on the acquired 3-D geometry. The electroanatomic maps of focal ATs demonstrate radial spread of activation, from the earliest local activation site in all directions (a well-defined early activation site surrounded by later activation sites; see Fig. 11.19). In these cases, activation time—the total range of activation times, from earliest to latest—is usually markedly shorter than the TCL (see Fig. 6.2). Conversely, a continuous progression of colors, with close proximity of earliest and latest local activation, suggests the presence of a macroreentrant tachycardia. In these cases, total activation time is in a similar range to TCL (see Fig. 12.13).

A stepwise strategy for mapping RA and LA focal tachycardias was described in a study using CARTO to avoid time-consuming whole-chamber map.³⁷ Using this approach, mapping is started with the acquisition of four or five anatomically defined sites at the superior and septal aspects of the tricuspid annulus, and the mapping procedure is strategically continued according to this initial activation sequence. If the initial four-point activation map shows the earliest atrial activation to be at the superior aspect of the tricuspid annulus, mapping is

continued toward the free wall of the RA, including the crista terminalis. When the earliest atrial activation within the four-point area is found at the septal aspect of the tricuspid annulus, mapping is expanded to the triangle of Koch and the paraseptal space. This strategy was found to differentiate reliably between ATs arising from the free wall of the RA, including the crista terminalis and RA appendage, from those arising from the triangle of Koch and paraseptal space, as well as from left-sided ATs. Once the general area of interest is identified, high-density mapping of this area is undertaken to identify the site of the earliest activation within this target area. If the unipolar electrogram at the point of earliest activation at the RA septum or at the high posterior wall still shows a significant R wave, or if RF ablation at that site is unsuccessful, a left-sided AT origin is assumed, and the procedure is extended to the LA.

Advantages

Electroanatomic mapping systems provide a highly accurate geometric rendering of the cardiac chamber with a straightforward geometric display that has the capability to determine the 3-D location and orientation of the ablation catheter accurately.

The capability of the mapping system to associate relevant EP information with the appropriate spatial location in the heart and the ability to study activation patterns (with high spatial resolution [less than 1 mm]) during tachycardia in relation to normal anatomical structures and areas of scar significantly facilitate the mapping and ablation procedure. It can suggest the mechanisms underlying the arrhythmia (distinguishing between a focal origin and macroreentrant tachycardia) and allows rapid visualization of the activation wavefront (propagation maps; Fig. 11.21), thus facilitating the identification of appropriate sites for entrainment mapping and pace mapping. High-resolution activation maps can be obtained in relatively short intervals by using multielectrode catheters (circular catheter or PentaRay) or basket catheter (Orion, Boston Scientific).³⁷

Furthermore, electroanatomic mapping systems provide the capability to create and tag several potential points of interest during the mapping process (e.g., sites with good pace maps) and return to them with great precision. These features provide significant advantages over conventional techniques. The catheter can accurately revisit a critically important recording site identified previously during the study, even if the tachycardia is no longer present or inducible and map-guided catheter navigation is no longer possible. In addition, fluoroscopy time can be reduced during catheter navigation, and the catheter can be accurately guided to positions removed from fluoroscopic markers.

Limitations

The sequential data acquisition required for creation of the electroanatomic map remains time-consuming because the process requires tagging many points, depending on the spatial details needed to analyze a given arrhythmia. Furthermore, because the acquired data are not coherent in time, multiple beats are required, and stable, sustained, or frequently repetitive arrhythmia is usually needed for creation of the activation map. Single PACs or nonsustained AT can be mapped, although at the expense of an appreciable amount of time. This can be facilitated by using multielectrode mapping catheters for data acquisition.

One difficulty with current methods is that incorrect assignment of activation for a small number of electrograms can invalidate the entire activation map; manual adjustment of activation times is often required to achieve the optimal representation. In addition, data interpolation between mapped points is used to improve the quality of the display; however, areas of unmapped myocardium are then assigned simple estimates of timing and voltage information that may not be accurate.

Fig. 11.21 Electroanatomic Mapping of Focal Atrial Tachycardia (AT). (A) Electroanatomic (CARTO) left atrial (LA) activation map in the posteroanterior view constructed during focal AT originating left aspect of the LA roof. During tachycardia, the activation wavefront propagates from the earliest local activation site (red) in all directions. (B–E) LA propagation map during the focal AT. LAA, Left atrial appendage; LIPV, left inferior pulmonary vein; LSPV, left superior pulmonary vein; RIPV, right inferior pulmonary vein; RSPV, right superior pulmonary vein.

In addition, the patient or intracardiac reference catheter can move, thus necessitating remapping. Although a shadow (to record original position) can be placed over this catheter to recognize displacement during the procedure, in which case the catheter can be returned to its original location, this may not always be feasible or accurate. Another limitation specific to the CARTO and Rhythmia systems is the requirement of a proprietary mapping catheter; no other mapping catheter types can be used with these systems. In contrast, the EnSite NavX system can work with most manufacturers' ablation catheters and RF or cryogenerators.

Mapping Nonsustained Focal Atrial Tachycardia

Several mapping modalities can be used when AT is short-lived or cannot be reproducibly initiated or when only infrequent PACs are being targeted by ablation, including simultaneous multisite data acquisition systems (noncontact mapping system, basket catheter, or high-density mapping). These mapping systems can also be used for sustained tachycardias, according to the operator's preference. Moreover, the electroanatomic mapping and pace mapping techniques discussed can be used in these situations.

Ensite Noncontact Mapping System

The EnSite 3000 noncontact mapping system (St. Jude Medical) consists of a noncontact catheter with a multielectrode array surrounding a 7.5-mL balloon mounted at the distal end. Raw data detected by the multielectrode array are transferred to a silicon graphics workstation via a digitalized amplifier system. The multielectrode array is used to construct a 3-D computer model of the virtual endocardium. The system can reconstruct more than 3000 unipolar electrograms simultaneously and superimpose them onto the virtual endocardium, thus producing isopotential maps with a color range representing voltage amplitude. Electrical potentials at the endocardial surface some distance away are calculated. Sites of early endocardial activity, which are likely adjacent to the origin of the AT, are usually identifiable. Noncontact mapping can rapidly identify AT foci and thus delineate starting points for conventional mapping.

The main advantage of noncontact endocardial mapping is its ability to recreate the endocardial activation sequence from simultaneously acquired multiple data points over a few (theoretically one) tachycardia beats, without requiring sequential point-to-point acquisitions. Therefore it can be of great value in mapping nonsustained arrhythmias, PACs, irregular ATs, and rhythms that are not hemodynamically stable.

Technique. The EnSite 3000 system requires placing a 9 Fr multielectrode array and a 7 Fr conventional (roving) mapping-ablation catheter in the cardiac chamber of interest. The balloon catheter is advanced over a 0.035-inch guidewire under fluoroscopy guidance and positioned in the atrium and deployed. The balloon is positioned in the center of the atrium and does not come in contact with the atrial walls being mapped. Aggressive anticoagulation with IV heparin is required to maintain the activated clotting time at 250 to 300 seconds for right-sided and 300 to 400 seconds for left-sided mapping.

The mapping-ablation catheter is positioned in the atrium and used to collect geometry information. The mapping catheter is initially moved to known anatomical locations (IVC, SVC, CS, HB, and tricuspid annulus for RA mapping and mitral annulus and PVs for LA mapping), which are tagged. A detailed geometry of the chamber is then reconstructed by moving the mapping catheter around the atrium. Using this information, the computer creates a model of the atrium.

After the chamber geometry is defined, mapping of the arrhythmia can begin. The data acquisition process is performed automatically by the system, and all data for the entire chamber are acquired simultaneously. The system then reconstructs unipolar electrograms simultaneously

and superimposes them onto the virtual endocardium, thus producing isopotential maps with a color range representing voltage amplitude. A default high-pass filter setting of 2 Hz is used to preserve components of slow conduction on the isopotential map. Color settings are adjusted so that the color range matches 1 to 1 with the millivolt range of the electrogram deflection of interest. The color scale for each isopotential map is set so that white indicates most negative potential and blue indicates least negative potential. Activation can be tracked on the isopotential map throughout the cycle to the onset of the tachycardia beat. Virtual electrograms are then reconstructed at sites of earliest activation on the isopotential maps to look for a unipolar QS pattern. If the atrial electrograms overlap with the T wave, a VES may be delivered to accelerate ventricular depolarization and repolarization and may reveal the following atrial complex without far-field interference.

Isochronal maps can also be created. These maps represent progression of activation throughout the chamber relative to a user-defined electrical reference timing point. Contact mapping using the conventional ablation catheter may also be performed at sites of interest to supplement noncontact mapping findings, and color-coded contact activation maps can be displayed on the same 3-D geometry. Once earliest activation is identified, the site is labeled on the 3-D map, and the locator signal is used to navigate the ablation catheter to it in real time during tachycardia or during normal rhythm when sustained tachycardia is not inducible.

The origin of AT is defined as the earliest site showing a single spot on the isopotential map and a QS pattern on the noncontact unipolar electrogram. Early sites with an rS pattern can represent foci that are epicardial in origin or early activation sites in an adjacent structure. The earliest site that shows an rS pattern with a sudden increase of peak negative potential on the noncontact unipolar electrogram after the AT depolarizes is considered to represent the "break-out point" or "exit" from the tachycardia focus, and the path between the origin and the break-out point likely represents the preferential pathway of conduction from the origin of the AT. As such, the traditionally defined origin of focal AT (by contact mapping techniques), whereby centrifugal activation occurs, potentially represents the breakout point, rather than the real origin of the tachycardia. Ablation at the origin of tachycardia or along the proximal path to the breakout point typically eliminates the arrhythmia.

Limitations. Very-low-amplitude signals may not be detected, particularly if the distance between the center of the balloon catheter and the endocardial surface exceeds 40 mm, thus limiting the accurate identification of diastolic signals. Furthermore, a second catheter is still required for additional mapping and for ablation. Aggressive anticoagulation is required using this mapping modality, and special attention and care are necessary during placement of the large balloon electrode in a nondilated atrium.

Multielectrode Basket Catheter Mapping

The basket catheter consists of an open-lumen catheter shaft with a collapsible, basket-shaped, distal end. The catheter is composed of 64 electrodes mounted on eight flexible, self-expanding, equidistant metallic splines. Each spline carries eight ring electrodes. The electrodes are equally spaced 4 or 5 mm apart, depending on the size of the basket catheter used (with diameters of 48 or 60 mm, respectively). Each spline is identified by a letter (from A to H) and each electrode by a number (from 1 to 8, with electrode 1 having the distal position on the splines). The basket catheter is constructed of a superelastic material to allow passive deployment of the array catheter and optimization of endocardial contact.

Technique. The size of the atrium is initially evaluated (usually with echocardiography) to help select the appropriate size of the basket

catheter. The collapsed basket catheter is advanced under fluoroscopy guidance through an 11 Fr long sheath into the RA or LA; the catheter is then expanded (eFig. 11.8). Electroanatomical relations are determined by fluoroscopically identifiable markers (spline A has one marker and spline B has two markers located near the shaft of the basket catheter). In addition, the electrical signals recorded from certain electrodes (e.g., annular or HB electrograms) can help identify the location of those particular splines.

From the 64 electrodes, 64 unipolar signals and 32 to 56 bipolar signals can be recorded (by combining 1–2, 3–4, 5–6, 7–8, or 1–2, 2–3, until 7–8 electrodes are on each spline). Color-coded activation maps are reconstructed. The concepts of activation mapping discussed earlier are then used to determine the site of origin of the tachycardia. The capacity of pacing from the majority of basket electrodes allows the evaluation of activation patterns, pace mapping, and entrainment mapping. The electrograms recorded from the basket catheter can be used to monitor changes in the activation sequence in real time and thereby indicate the effects of ablation as lesions are created.

After basket catheter deployment, the conventional catheters are introduced and placed in standard positions. The ablation catheter is placed in the region of earliest activity and is used for more detailed mapping of the site of origin of the AT (see eFig. 11.8).

Limitations. The electrode array does not expand to provide adequate contact with the entire atrium. In addition, the system does not permit immediate correlation of activation times to precise anatomical sites. Furthermore, a second catheter is still required for additional mapping and for ablation. The use of basket catheter mapping has largely been replaced by contact and noncontact electroanatomic mapping technologies.

ABLATION

Target of Ablation

The site of origin (or focus) of focal AT is the target of ablation. Bipolar electrograms at the site of successful ablation are typically fractionated and demonstrate moderate to marked presystolic timing. Average presystolic intervals at successful ablation sites are generally longer than 30 milliseconds (but not mid-diastolic, unlike MRAT). However, the key to successful mapping is finding the earliest site because there is great variability in the presystolic interval that will be obtained at successful ablation sites (10 to 40, but rarely as much as 80 milliseconds). QS unipolar electrogram morphology is highly predictive of the successful ablation site and supplements findings of bipolar mapping. Timings of the earliest bipolar and unipolar electrogram should be in agreement (see Fig. 11.13).

Focal ATs arising from the PVs can be targeted by either focal ablation or electrical isolation of the culprit PV. The latter approach can potentially limit the risk of PV stenosis, especially when targeting more distal foci within the PV.

Ablation Technique

For catheter ablation in the focal AT, a nonirrigated 4-mm-tip ablation catheter is usually used. Large-tip or irrigated ablation catheters can be of value for ablation of foci at the crista terminalis. Standard RF power delivery is adjusted to achieve a tip temperature of 55°C to 65°C. The response of the AT focus to a successful RF application should be rapid, typically within a few seconds of RF application. The most common response to successful ablations is abrupt termination. However, in some patients, transient acceleration precedes termination; in others, gradual slowing precedes termination (Fig. 11.22). If the tachycardia is not affected within 10 to 20 seconds, RF energy application is terminated, and the catheter is repositioned slightly for a repeat attempt.

Prolonged RF applications beyond 20 seconds without accompanying changes in AT rate are usually nonproductive.

Extensive ablation in one area that does not terminate AT may cause enough damage to block the spread of activation partially in the region, thus causing a change in P wave morphology (although the actual focus may not have changed), as well as slow propagation of the tachycardia impulse away from the focus of the tachycardia to activate atrial myocardium. The latter effect can result in an increase in the interval between the presystolic electrogram at the focus and P wave onset (Fig. 11.23).

If the AT terminates or changes rate noticeably during the 10-second ablation, the RF application is continued for 30 to 60 seconds. However, in some patients, applications that may be just slightly off-target can cause acceleration of the AT without terminating it. In these cases, the tachycardia rate usually remains accelerated as long as the RF application is in progress, and it returns immediately to the baseline rate when the RF delivery is discontinued. If adequate catheter tip temperature is achieved and good contact is ensured (which can be assessed by observing ST elevation on the unipolar recording), this probably suggests that the catheter is close to, but not exactly at, the proper target area. Continued RF application at a site that produces only acceleration (but not termination) after 15 seconds invites the possibility of transient injury to the AT focus that impedes further ablation and can result in later AT recurrence.

Intracardiac echocardiography (ICE) can be useful to provide focused real-time images of the endocardial surfaces critical for positioning of catheters, establish catheter tip–tissue contact, and monitor energy delivery in the beating heart. In particular, ICE has been used in cristal ATs. In view of the variability in the anatomical course of the crista terminalis, ICE can assist in accurate positioning of the multipolar mapping catheter and guide precise mapping along this structure with the mapping-ablation catheter (eFig. 11.9).

Ablation of Para-Hisian Atrial Tachycardias

Para-Hisian ATs (i.e., ATs with earliest activation in the region of the HB) generally originate from the superior paraseptal area of the atria, in the space delineated between the anterior superoseptal RA, the anterior superoseptal LA, and the noncoronary sinus of Valsalva, likely corresponding to the embryological retroaortic node (remnants of nodal-type AV canal myocardium in the region of the right fibrous trigone).³⁸ Propagation of atrial depolarization from the tachycardia focus occurs almost simultaneously to the para-Hisian RA, the antero-septal LA, and the noncoronary aortic sinus of Valsalva. Therefore, when the site of origin of AT is mapped to the mid or anterior RA septum, mapping should be extended to noncoronary aortic sinus of Valsalva, LA, or both, before starting ablation in the vicinity of the AVN or HB (Figs. 11.24 and 11.25). This is especially important when the presystolic activity is not particularly early (i.e., less than 20 milliseconds pre-P wave onset), the unipolar electrogram does not show an early QS configuration, or when multiple sites with a 15-mm radius have similar activation times.^{21,22,39,40}

Focal ATs arising from the anterior RA septum and para-Hisian regions can be amenable to catheter ablation from multiple approaches including the superoseptal aspect of the RA (posterior to the HB), aortic sinuses of Valsalva (especially noncoronary sinus of Valsalva), or antero-septal part of the LA (aortic-mitral junction). Recent reports have demonstrated that most of those foci can be eliminated by RF ablation within the noncoronary cusp. The aortic root is centrally located with the noncoronary aortic sinus of Valsalva abutting the superior paraseptal region between the RA and the LA, providing an optimal “vantage point” with excellent catheter stability and tissue contact that is relatively removed from the AVN, thus limiting the risk of AV block. Therefore when activation timing at the noncoronary aortic sinus of

eFig. 11.8 Basket Catheter (BC) Mapping of Atrial Tachycardia (AT). *Upper panels*, Fluoroscopic views (right anterior oblique [RAO] and left anterior oblique [LAO]) of the BC positioned at the ostium of the left superior pulmonary vein (PV). *Lower panel*, BC bipolar electrograms (1–2, 3–4, 5–6, 7–8) from the eight splines (A to H) are displayed. The earliest atrial activation during AT is recorded by the proximal electrodes of the E spline of the basket catheter. Detailed mapping obtained by the ablation catheter (ABL) recorded an even earlier activation (*dashed line*) at a site in the left atrial roof just outside the PV ostium. Radiofrequency energy delivery at that site resulted in termination of the tachycardia within a few seconds. CS_{dist} , Distal coronary sinus; CS_{prox} , proximal coronary sinus.

eFig. 11.9 Intracardiac Echocardiographic for Ablation of Cristal Focal Atrial Tachycardia. Intracardiac echocardiographic view (using the mechanical radial imaging system) of the high crista terminalis (*CT*) showing the anatomical structures and location of the ablation catheter (*ABL*) at the site of radiofrequency application (*right panel*). The ablation catheter is located on the high lateral CT. *AO*, Aorta; *LA*, left atrium; *RA*, right atrium.

Fig. 11.22 Catheter Ablation of Focal Atrial Tachycardia (AT) Originating From the Superoanterior Aspect of the Mitral Annulus. Four surface electrocardiogram leads and intracardiac recordings from a catheter in the coronary sinus (CS) and a 20-pole Halo catheter positioned around the tricuspid annulus (TA) are shown. Radiofrequency (RF) energy delivery at the successful ablation site resulted within a few seconds in acceleration then slowing of the tachycardia rate followed by termination of the AT and restoration of sinus rhythm. ABL, Ablation site; dist, distal; prox, proximal.

Fig. 11.23 Recordings From Focal Right Atrial Tachycardia During Progressive Ablation. Examples are shown from selected ablation sites. Site 2 shows tachycardia from high right atrium (HRA) with a site 26 milliseconds prior to the P wave onset. Ablation here changed the P wave morphology as shown in subsequent examples, and progressive ablation at sites in the lateral right atrium resulted in lengthening of the interval from electrogram to P wave onset (up to 92 milliseconds). Note also progressive fragmentation of the bipolar ablation recording and degradation of the unipolar recording. Abl_{dist}, Distal ablation site; Abl_{prox}, proximal ablation site; Abl_{uni}, unipolar ablation site.

Valsalva is similar to, or even slightly (less than 10 milliseconds) later than, that at the RA septum, initial ablation at the noncoronary aortic sinus of Valsalva is preferred. Coronary angiography may be considered to delineate aortic sinus of Valsalva anatomy prior to ablation. Alternatively, ablation can be safely and effectively accomplished with ICE guidance.^{22,23,38,41–43}

When the noncoronary aortic sinus of Valsalva approach fails, mapping of the LA may be considered, with attention to the aorto-mitral continuity. If activation is late in the LA (and ablation in the noncoronary aortic sinus of Valsalva is not successful), then ablation in the RA septum may be considered using cryoenergy or careful applications of RF energy.^{38,41,42}

Fig. 11.24 Anatomical Relationship of the Anterior Right Atrial (RA) Septum and Para-Hisian Regions. (A) Transesophageal echocardiography (TEE) showing the interatrial septum in relation to the aortic root and noncoronary aortic sinus of Valsalva (N). (B) Intracardiac echocardiography (ICE) showing mapping catheter positioned in the anterior RA septum (yellow arrow) in the His bundle region, and a second catheter positioned in the immediate left aspect of the septum (green arrow). Notice the close relationship of the noncoronary cusp sinus of Valsalva (N). (C and D) Right (RAO) and left (LAO) anterior oblique fluoroscopy views of mapping catheters positioned at the para-Hisian region (yellow arrows) and anteroseptal part of the left atrium (green arrows). L, Left sinus of Valsalva; R, right sinus of Valsalva.

Ablation of focal ATs near the AVN or HB (in the triangle of Koch) requires special precautions. Titrated RF energy output should be used, starting with 5 W and increasing by 5 W every 10 seconds of energy application, up to a maximum of 40 W. In addition, it is preferable to deliver RF energy during AT; if AT terminates during RF delivery, the RF application is continued at the same power output for 30 seconds and then repeated for 30 seconds or more. If the AT does not terminate with an RF output of 40 W for 30 seconds, then another site should be sought. If accelerated junctional rhythm develops after AT termination, overdrive atrial pacing should be performed to monitor AV conduction, or RF application should be stopped and other sites sought.

To reduce the risk of AV block, RF delivery should be immediately discontinued when (1) impedance rises suddenly (more than 10 Ω), (2) the PR interval (during NSR, atrial pacing, or AT) prolongs, (3) AV block develops, (4) retrograde conduction block is observed during junctional ectopy, or (5) fast junctional tachycardia (CL shorter than 350 milliseconds) occurs because it may herald imminent heart block.

Endpoints of Ablation

Tachycardia Termination

Sudden termination of a sustained AT during RF application suggests a successful ablation. However, reliance on AT termination during RF application as the sole criterion of successful ablation may be misleading because AT may terminate spontaneously or in response to PACs induced by the RF application; hence tachycardia termination may not be a result of ablation of the AT focus. Furthermore, sudden termination of the AT can be associated with catheter dislodgment from the critical site to another site, thus making it difficult to deliver additional lesions at the critical site.

Noninducibility of Tachycardia

To use this criterion as a reliable endpoint, careful assessment of inducibility should be performed prior to ablation; the feasibility and best method of reproducible induction of the AT should be documented at baseline before ablation. In the setting of easy inducibility prior to

Fig. 11.25 Focal Atrial Tachycardia (AT) Arising From the Noncoronary Aortic Sinus of Valsalva (SOV). *Top panel*, Intracardiac recordings with the ablation catheter positioned at the His bundle (HB) region (*left*) in the anterior right atrial (RA) septum, and then in the noncoronary aortic SOV (*right*). Note that local activation in both regions is presystolic, preceding the onset of the tachycardia P wave, but the timing in the noncoronary SOV is earlier than that at the HB region. *Middle panel*, Electroanatomic activation maps using the CARTO system during sustained AT. (A) Activation mapping was initially performed in the RA, with the earliest local activation in the HB region. (B) Activation mapping is extended to the left atrium (LA) which showed similarly early activation timing at the left side of the atrial septum. (C) Activation mapping is then extended to the noncoronary aortic SOV, where the earliest local activation is seen. *Lower panel*, Radiofrequency catheter ablation at the focus of the AT in the noncoronary aortic SOV instantaneously terminated the tachycardia. AbI_{dist} , Distal ablation; CS_{dist} , distal coronary sinus; CS_{prox} , proximal coronary sinus; MA , mitral annulus; TA_{dist} , distal tricuspid annulus; TA_{prox} , proximal tricuspid annulus.

ablation, one may consider the lack of inducibility as an indicator of successful ablation. Noninducibility of the arrhythmia is inapplicable if the original arrhythmia was not inducible at baseline or was inadvertently terminated mechanically. Tachycardia inducibility should be reassessed 30 minutes after the last successful RF application.

Elevated Pacing Threshold

During pace mapping prior to ablation, if the pacing threshold was assessed and the catheter did not move after successful ablation at that site, pacing can be repeated. Elevation of pacing threshold (at least doubling) can be used as an index of completeness of elimination of viability of the target tissue. If the pacing threshold has not changed, one may consider additional ablation at the site to insure there has been adequate damage to the area. This has not been studied in any systematic way, however.

Outcome

The short-term success rate is variable (range, 69% to 100%; mean, 91%). Complication rates range from 0% to 3% (mean, 3%). Recurrence rates range from 0% to 25% (mean, 9%). The anatomical location of the AT focus influences the outcome.

Atrioventricular Block

AV block can complicate ablation of ATs originating in the vicinity of the AVN or HB. Ablation in the noncoronary aortic sinus of Valsalva or aortomitral continuity can potentially eliminate para-Hisian ATs with lesser risk of AV block. When ablation within the triangle of Koch is attempted, titrated RF energy output and RF application for short duration should be used, coupled with overdrive atrial pacing to monitor AV conduction in case accelerated junctional rhythm occurs. Alternatively, cryoablation may be used with its slightly better safety margin for AV conduction and, moreover, detailed mapping in the right and left anterosseptal regions, because ATs arising along the anterior and anterosseptal LA and even the right superior PV frequently have earliest RA activation at the HB region, with a normal activation pattern along the posterior LA, as recorded by the CS electrodes.

Phrenic Nerve Injury

The right phrenic nerve descends between the parietal pericardium and parietal pleura along the lateral side of the RA between the right superior PV and SVC. When ablation is planned in this region, high-output (10 mA) pacing should be performed prior to RF application.⁴⁴ The ability to pace the phrenic nerve at a candidate ablation site should prompt attempting to find a slightly different site or, if this is not possible, applying RF energy at low power or for a short duration. Even when the phrenic nerve cannot be paced, intermittent fluoroscopic visualization of the ipsilateral diaphragm movement should be performed during

RF application at high-risk sites, and RF delivery should be terminated if diaphragmatic excursion decreases. An alternative approach is to position a catheter in the SVC at a site at which the phrenic nerve can be consistently captured and pace the phrenic nerve during ablation. RF energy delivery should be stopped immediately if diaphragmatic contraction becomes less vigorous or ceases. Early recognition of phrenic nerve injury during RF delivery allows the immediate interruption of the application prior to the onset of permanent injury and is associated with rapid recovery of phrenic nerve function. If phrenic nerve injury prohibits ablation at desired endocardial sites, displacement of the phrenic nerve from the ablation target site via by saline injection or balloon or electrode catheter placement in the pericardial space (through the subxiphoid approach) may be considered.

Sinus Node Dysfunction

Sinus node dysfunction can develop during ablation of ATs originating near the sinus node. The risk is usually low because of the diffuse distribution of the sinus node complex, except in older patients or in those with preexisting sinus node dysfunction.

Video 11.1 Focal Atrial Tachycardia: CARTO Activation Mapping. At right, 3-D electroanatomic (CARTO 3) activation map of the right atrium (RA) constructed during focal atrial tachycardia (AT). During tachycardia, point-by-point activation mapping is performed by sampling the location of the catheter together with the local electrogram from a plurality of endocardial sites. Each selected point is tagged on the 3-D map. The local activation time at each site is determined from the intracardiac bipolar electrogram and is measured in relation to the fixed reference electrogram. The acquired local activation times are color-coded and superimposed on the anatomical map with red indicating early-activated sites, blue and purple late-activated areas, and yellow and green intermediate activation times. Known anatomical points, such as the His bundle and tricuspid annulus, are tagged to serve as landmarks for the electroanatomic map. Note that the tachycardia terminates twice during the mapping procedure with catheter manipulation close to the focus of the AT (denoted by red color on the electroanatomic activation map). Burst atrial pacing is utilized to re-induce the tachycardia to continue the mapping procedure.

Organized atrial tachycardias (ATs) are broadly categorized as either focal or macroreentrant. Focal ATs exhibit a centrifugal activation pattern originating from a discrete site, and can have automaticity, triggered activity, and microreentrant mechanisms. A macroreentrant AT incorporates a relatively large reentrant circuit around a central obstacle. Depending on whether or not the cavotricuspid isthmus (CTI) is critical to the reentry circuit, macroreentrant ATs are divided into two groups: “CTI-dependent” or “non-CTI-dependent” macroreentrant AT (see **Table 11.1**). CTI-dependent macroreentrant ATs include typical atrial flutter (AFL), lower loop reentry, and intra-isthmus reentry.¹

The term “atrial flutter” has traditionally been used to refer to a continuously waving pattern on the electrocardiogram (ECG), without an isoelectric baseline in at least one lead, whatever the tachycardia cycle length (TCL). “Typical AFL” is reserved for a macroreentrant circuit with the activation wavefront rotating clockwise or counterclockwise around the tricuspid annulus and using the CTI as an essential part of the reentry circuit. “Atypical AFL” is only a descriptive term for an AT with an ECG pattern of continuous undulation of the atrial complex, different from that in typical AFL. However, the term “atypical AFL” introduces unnecessary confusion, and a mechanistic description of the AT circuit in relation to atrial anatomy is preferred.^{1,2}

PATHOPHYSIOLOGY

Right Atrial Anatomy

The right atrial (RA) endocardial surface is composed of many orifices and embryonic remnants, accounting for an irregular, complex surface.

The RA endocardium is architecturally divided into three anatomically distinct regions; each is a remnant of embryological development. The posterior smooth-walled RA, derived from the embryonic sinus venosus, receives the superior vena cava (SVC), the inferior vena cava (IVC), and the coronary sinus (CS). It also contains the fossa ovalis, the sinus node, and the atrioventricular node (AVN). The anterolateral trabeculated RA, derived from the “true” embryonic RA, is lined by horizontal, parallel ridges of muscle bundles that resemble the teeth of a comb (the pectinate muscle). It contains the RA appendage and free wall. The atrial septum is primarily derived from the embryonic septum primum and septum secundum.

The SVC enters the roof of the RA between the base of the RA appendage and the superior margin of the interatrial septum. The IVC enters the posterolateral portion of the floor of the RA along the inferior margin of the interatrial septum. The orifice of IVC is guarded by a fibrous or fibrous-muscular semilunar flap, the valve of the IVC (the eustachian valve). The CS enters the inferior aspect of the RA adjacent to the inferior margin of the interatrial septum, slightly more anterior and medial relative to the orifice of the IVC, and closer to the tricuspid annulus. Commonly, the CS orifice is guarded by a semilunar valve, the valve of the CS (valve of Thebesius). On the lower third of the interatrial septum lies the fossa ovalis (**eFig. 12.1**).^{3,4}

The posterior smooth-walled RA and the anterolateral trabeculated RA are separated by the crista terminalis on the lateral wall and the eustachian ridge in the inferior aspect. The sulcus terminalis, where the sinus node is located, is a subtle groove on the epicardial surface of the heart corresponding to the crista terminalis. The crista terminalis

Opened right atrium: right lateral view

3. Fossa ovalis
4. Inferior vena cava
5. Opening of coronary sinus
6. Pectinate muscles
7. Septal cusp of tricuspid valve
8. Crista terminalis
9. Right auricle

Comment: The smooth portion of the right atrium is known as the sinus venarum because it develops from the embryonic sinus venosus and receives blood from the superior and inferior venae cavae, and coronary sinus. It is separated from the more muscular portion of the atrium proper by a line, the crista terminalis.

The fossa ovalis is the adult representation of the embryonic foramen ovale.

Although the right atrium is slightly larger than the left atrium, it has thinner walls because the pressure on the right side of the heart is normally lower than that on the left side.

The auricle is a pouch-like appendage of the atrium but is functionally identical to the rest of the atrium.

Clinical: Atrial septal defects make up 10%–15% of congenital cardiac anomalies. In such cases, blood flows from the higher-pressure left atrium into the lower-pressure right atrium.

F. Netter M.D.

eFig. 12.1 Right Atrial Anatomy. (From Netter Images [www.netterimages.com], with permission.)

is a roughly C-shaped, convex, thick muscular band that runs from the high septum, anterior to the orifice of the SVC superiorly, and courses caudally along the posterolateral aspect of the RA. In its inferior extent, it courses anteriorly to the orifice of the IVC. The crista terminalis can vary in size and thickness, most often appearing as distinct ridge, but occasionally can be a broad, a flat, or a thin structure. As the crista reaches the region of the IVC, it is extended by the eustachian valve and eustachian ridge.

The eustachian valve is the remnant of the embryonic sinus venosus valve, which manifests as a flap of variable thickness and mobility along the orifice of the IVC; this valve can continue as a ridge (eustachian ridge) superiorly along the floor of the RA to the CS os, to join the valve of Thebesius, forming the tendon of Todaro, and then continuing onto the interatrial septum as the inferior limbus of the fossa ovalis.^{3,4} The tendon of Todaro is a fine, tendinous cord that runs as an extension of the free-edge of the eustachian ridge toward the central fibrous body. Its insertion into the central fibrous body marks the position of the compact AVN at the apex of the triangle of Koch.⁴
